Having re-entered ham radio after a 30 year hiatus, I would like to ask about RG/8U versus other cable types for use in a simple dipole or G5RV installation with 100W max. transmitter output. In the "good old days" Low loss "8U" was sort of the standard. There are some newer cable designations now.

Is there a better "standard" cable for the above use than RG/8U (specifically Belden 9913 low loss)?

RG-6 will take the legal limit on at least 80 and 160m and probably on
40m. It is available in direct burial type. The new, weather-proof
crimp on connectors are wonderful.

Several companies make or sell the PL-251 to F connector adaptors.

W8JI had some informative technical posts on the subject on the topband
reflector a few months back.

3876. How much does a counterpoise radiate?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-07 23:35:31 UTC
From: HB9DST <pgschreier@swissonline.ch>
Message-ID: <1175988931.788981.282780@n59g2000hsh.googlegroups.com>
Source record: 43392

Antenna restrictions here in HB9-land are severe, but I want to get on the air from my 3rd-floor apartment. I have draped a horizontal longwire outside along the wall of the building. This wire is now just short of 20m.

Before I transmit, I want to make sure to minimize any RFI that bothers the neighbors' stereo systems and other electronic equipment. First, I will put on a lowpass filter at the tx.

Past experience at other QTHs tell me that I will also need a counterpoise. But here's the question: does the counterpoise radiate, even if it's cut to 1/4 wavelength? Then, if I put the counterpoise on the floor in my shack I haven't really solved the problem because the CP radiates into my shack and my neighbors' apartments?

I realize that a counterpoise is the "second half" of an antenna. That being the case, what's the difference between a traditional dipole and a longwire/counterpoise configuration? Both legs radiate, correct?

Thanks for any clarification anyone can shed on this mystery!

For feeding a G5RV if the feedline is not much over 100 feet almost any coax is good enough. Probably would not use the rg-58 , but would use rg-8X or any of the rg-8 type coax. Would not waste the money on anything beter as you would only gain a couple of tenths of a db if that much.

The 9913 is hollow inside and may be hard to keep the water out of. I had some up for about 10 years and used it on 2 meters for ssb. It never did get any wate rin it for me. I don't like the LMR 400 as the center conductor is copper coated aluminum. Nothing wrong with that when it is installed correctly, but I just do not like it. Davis makes some Burry Flex that is very good, but over kill for the dipole. I just installed 4 beams using about 500 feet of it, triband for 20,15,10, a 432 mhz, 144 mhz and a 6 meter beam. Would not have used it on the triband but wanted to just buy one type of coax for the job.

Think I would use the rg-8X for the g5rv. I am feeding an 80 meter dipole and also an off center fed dipole with the rg-8x running about 700 watts out of a Heathkit sb200 amp.

Tom you are confusing grounding with bonding, the plumbing should be bonded to ground but not used for ground, at least this is getting to be the rule in most places. I know that using the plumbing for ground is still acceptaable in places and in a lot of places it is still acceptable if if the local code permitted it at the time it was installed(grandfathering)..

I would think the power level would be more voltage limiated. Most of the
rg6 is rated around 300 to 350 volts. This is about 1200 watts on a matched
line. derate for a swr of say 3 or 4 to 1 and you get to run about 300 to
400 watts into it,

Sure it does, what happens when a plumber replaces a piece of metal pipe with plastic and opens your ground. The plumber has no responsibility to see if the plumbing is being used for ground. Mrtal plumbing should be bonded to the electrical ground, not be the ground.

I would not recommend putting very long aerials on to a Freelander as they
can easily hit bridges when the car is on the back of a breakdown.

My article at http://www.vk1od.net/G5RV/index.htm models the efficiency
of a number of feed options for G5RV, it may provide the answer to your
questions.

Re a "simple dipole" (if that means a half wave dipole, a one band
antenna), I currently use an inverted V dipole on 40m. It is shortened to
cause VSWR=1.5 on RG6 feedline (75 ohm), and the RG6 feedline is of
length (21m) that transforms the feedpoint impedance to nominal 50 ohms
to connect directly to the amplifier (AL-811H) (VSWR<1.1 at band centre).
The RG6 has a heap of suppression sleeves threaded over the load end as a
W2DU style balun. Total feedline + balun loss is 0.4dB. There are simple
solutions out there, and feedline doesn't come cheaper than RG6 at US
$0.20/m here in Oz (but you need to be selective in choosing RG6 for this
purpose).

Hi Paul,

Yes, absolutely. How much the contribute to radiation is a matter of
phase contributions. The many elements (or spokes) of a ground plane
will tend to cancel their radiations in the far field, but absolutely
every inch of everyone of them radiates. For "the other half" you
will not achieve this cancellation, except in some directions (given
the classic dipole's figure 8 pattern).

I bought a rotor and controller at a hamfest.
It is a Cornel Dublier Electronics H3/CD44 Series 2.
The position indicator doesn't move with rotation,
the indicator needle is almost full scale and can be moved
with the calibration adjustment.
I suspect the problem is in the rotor.
I need a description of operation, to try and troubleshoot the unit.
The function of the 8 connections would help.
A schematic would be even better.

Thanks, Mike

Interesting that you think that vertical is the best polarization for mobile operation. I have done a lot of testing on 2 meters with equal gain end to end that would indicate that you are quite mistaken. Horizontal polarization from a fixed station to a mobile, or a mobile station to a mobile is much more effective if horizontally polarized. The reasons for this are well documented, so I won't go into that. The most obvious notable difference is that "picket fence" fading is much worse when vertically polarized.

The major reason vertical polarization is used (for FM) is that it is easy. SSB/CW on VHF/UHF is still horizontal when mobile.

I have recently found that terminals 3 and 7 are a 500 ohm pot in the
rotor, don't yet know which is the wiper. Also 4 and 8 are the motor
capacitor.

Go here and download the manual. It is for a Hy-gain 45 but it should be
the same schematic for the 8 wire rotator. Most of the CDE and Hy-gain
rotators ues the same basic electric design and the mechanical part is
differant .

Owen,

Are you saying that those who support my explanation of stub matching are telling lies!? I can't believe you said that.

I explained this exact matching function in great detail in October 1974 QST. It was repeated in Reflections
edition 1 in 1990, and again in edition 2 in 2001. It was also published in QEX in the Mar/Apr 1998 issue.

I had to submit my manuscripts to the engineering departments of four different divisions of RCA for approval
before being allowed to even submit them to QST to determine if they were interested in publishing them. One
of the RCA engineers who reviewed my text was Jack Young, then the chief engineer of the transmitter section
of the RCA Broadcast Engineering Division. He complimented me on my explanation of stub matching using the
reflection coefficients as the parameters. On accepting my papers for publication in QST, the former Technical
Director of the League, George Grammer, W1DF, also complimented me on the unique approach explaining stub
matching, and also for my explanation of conjugate matching. Grammer was probably the most highly educated
engineer ever gracing the ARRL.

It's been 33 years since I published my presentation using reflection coefficients, and to date no one except
some of the posters on this NG have disputed it. Are you saying that all who reviewed my writings that
appeared in QST and in Reflection were being lied to?

You suggested walking through the Smith Chart with the problem. Owen, the Smith Chart is Fig. 1 in my
presentation that proves my position is correct. Please review the QEX article I referenced above to see it.
With all due respect, Owen, I believe you have misunderstood, or perhaps misconstrued the procedure I
presented. Would you please review it again to see where you might have gone wrong?

Owen
Thanks for the advice.
My new second antenna is the original I put up: specifically a
store-bought folded dipole from DX Engineering. It is placed orthogonal
(90 deg away from) to the existing G5RV and about 20 feet closer to the
ground. I am using RG / 8U to a 4:1 Balun to 300 Ohm balanced feedline
to the folded dipole. I cut the 300 ohm feedline to optimize the folded
dipole fo 30M and above.

I appreciate the response.

Hi Walt,

I have reviewed Chapter 3 of Reflections II which you kindly sent me. I think it contains the deveopment to which you refer.

It seems to me that Chapter 3 depends entirely on an assumption that the phase relationship of the current and voltage of a travelling wave is 0 deg or 180 deg, depending on the direction. This only holds true for lossless lines and distortionless lines, and so the "proofs" developed in the chapter are not general proofs. For example, the proof that reflected power is purely real and of magnitude |E-|^2/Zc is not developed for the general case, and happens to not be correct for the general case.

Hi John,

Some useful information and history is here:
http://en.wikipedia.org/wiki/Coaxial_cable. For a given type, you'll find quality all over the map, from decent to downright crummy. That said, I recommend a looking at a prospective manufacturer's datasheet before buying. If there are no specifications available, keep looking!

When it comes to loss/length (for a given cable type), foamed polyethylene dielectric will be better. Percentage of shielding is probably the next determining factor. An aluminum foil shield of course will be 100%, but won't take much flexing before fracturing. Save it for long runs that are secured in place, and use braided copper or braided copper + foil for other uses. You'll find most all manufacturers make cables with as much as 97% braided copper shielding. The last item of concern will be the outer jacket. PVC is the most common. Some are "non contaminating" or "UV resistant" types that degrade much slower in sunlight. Use a UV-resistant type for outdoor applications.

Belden 9913 has a "Semi-Solid Polyethylene" dielectric and can't handle tight-radius bend. It also has a solid center conductor, which doesn't like repeated flexing. The shield is "100% coverage Duobond tape" (foil), which also doesn't like repeated flexing.

RG-58 types are rated to 250W (under matched conditions) safely. If you plan on running higher power and/or longer runs and/or high standing waves on the feedline, you should consider something larger. Many hams have used RG-8X (also called "mini RG-8") with good success. If you're cost-conscious, this might be a good choice.

Ralph mentioned LMR400 as having a copper coated aluminum center conductor. It's made by Times Microwave Systems (http://www.timesmicrowave.com/) and is a solid conductor. Their Ultraflex version (LMR400UF) has a stranded bare

copper inner conductor. He also mentioned Davis RF
(http://www.davisrf.com/) having Buryflex available. As far as I can see,
it's LMR400UF with a different brand name on it. By the way, I've dealt
with them once... very good folks.

Correct. If you call it a "counterpoise" instead of "the second half of
the antenna", it changes nothing but the name. It is still the same
wire, and will radiate exactly the same in both cases.

However much RF current you manage to push into the part of the antenna
that you do want to radiate, you can be sure that an equal current is
flowing into the other part... or maybe into the mains wiring.

personally I dont consider it for ham work it appears too far out of
spec and cannot be gaurentead to be outdoor rated ie if ordered and
the supplier does not have they may send the wrong type. In a
warehouse you pay peanuts get monkeys. power wise take the 300 watts
and 1/2 it for safety limits.

Lucky Mark. He has copycats who also do not use a spell check program. This guy could be vying to be his twin.
And the comment was made that RG-6 is easily purchased in many of the local Big Box home outlet stores.
And had you researched this further, you'd have seen the comments by Hams who have succesfully used RG-6 for HF use that includes power outputs of up to 1,500 watts with no deleterious effects upon the cable.
One Ham claims that he has been using this very cable for many years with no problems whatsoever.
Sorry, but I will use this cable and find out for myself. And, no, I won't "1/2 it for safety limits."
Wherever did you come up with this out-of-the-hat number, anyway?

Name and Callsign withheld to avoid spamming and stalking by You-Know-Who.

> An expat-American cliffdweller in Switzerland

Hello Paul,

You are fully right, the current that goes into your CP wire does radiate. With regards to nearby interference, you also have to incorporate the near fields.

First you can reduce the current into the CP by using a halve wave radiator. That has kOhms of input impedance, hence reducing the current into your CP by about 8. So the 20m wire is not a good choice for 80m.

Other option is to use more wires to emulate a star configuration, the current in the wires reduce and the resistive part of the CP (reducing losses). But there is more. When you use for example 4 wires, the currents in the opposite CP wires, flow in opposite directions, reducing total radiated field. Because of lower current, near field does reduce also.

I think the best option is to connect as much as metal (fences, concrete wire grid, etc) to each other. The goal is to spread the CP

current as much as possible over the apartment building (in both horizontal and vertical direction).

How far is the antenna wire from the wall? If it runs parallel, the radiation will go into the building again (if there is no reinforcing wire mesh present). When it runs too close to the wall, the wall will absorb significant part of the power and/or unintended radiation from domestic electronic equipment will enter your antenna.

Best Regards,

Wim

Thanks Ralph,
At first glance the manual seems to be identical except for the mechanical
as you mentioned.
Interesting how they grounded the wiper of the positioning pot. That's not
what I would have been looking for if I started troubleshooting without a
schematic.
Thanks again, Mike

Do Born and Wolf offer crisp definitions of the boundaries
between coherent, partially coherent, and mutually incoherent?

Or is it a continuum arbitrarily divided into 3 regions for
the purposes of discussion?

...Keith

The local Home Depot here sells RCA branded RG6 that is meant for outside use. As far as power goes, skinny little RG174 is rated at ~200W. The RG6 has got to be at least that good.

Another way to look at it, without the counterpoise, you may have
trouble getting the swr down to a reasonable level, and the rig may be
very rf-hot. I recently played with an end-fed wire on 20 meters, I
believe it was 3/4 wavelength long, and without a 1/4 wave
counterpoise on the tuner's ground lug, it was untuneable. With the
counterpoise, it worked.

Just on the off chance does anyone know what these antennas have inside them?

I could do with knowing and am not really in a position right now to pull one apart and find out.

To me logic says they're just simple monopoles, and they definitely don't present 50 Ohms across the frequency coverage in the specification (25-1900MHz), which suggests to me that there isn't any matching network in the base.

I've stuck one on my analyser, but of course that wouldn't show up any matching network, though it does show the main resonance at 145MHz ;-)

Comments would be appreciated. :-)

Once you have the schematic you will be able to troubleshoot the
problem easily. It is most likely the wirewound pot in the rotator
mechanism. I simply cleaned mine for years of continued good operation.
Be careful when you open the rotator though -- do it over a baking pan
or something with a lip on it as some bearings are likely to fall out.
They are easy to set back during reassembly.

Owen, your statement that my writings in Reflections are flawed is shocking. The feeling I get from it is like
getting sucker punched in the stomach.

Are you so narrowly oriented academically that the difference between lossless and low-loss conditions is so
great that general principles cannot be applied to situations where real-world low-loss elements are involved?

It is generally accepted that voltage and current travel forward on a low-loss line with 0ï¿½ phase difference.
In low-loss lines the effect of the small negative-reactance component in the Z0 due to the loss is routinely
disregarded as insignificant. Likewise, when voltage and current travel rearward on a low-loss line, resulting
from reflection at a mismatched termination, it is generally accepted that they travel with a 180ï¿½ phase
difference, disregarding the small error caused by the insignificantly-small reactance in the Z0.

Calculations performed when disregarding the small error still yield practical results in hands-on operations.
On the other hand, if everyday practical operations required calculating with the academically-perfect
conditions of the Z0, time would be lost due to the unnecessary complications involved in the calculations.

Your stated position is that applying general principles that are academically correct only with lossless
elements to operations involving low-loss elements is flawed.

C'mon, Owen, let's get practical and rescind your impeachment of Reflections.

Of course, you can give examples where the waves survive the
superposition. But what we are talking about is when the waves do
NOT survive the superposition.

How about wave cancellation, Gene? When two coherent waves traveling
in the same direction in the same path with equal magnitudes and
opposite
phases interact, they cease to exist in the direction of the original
travel.
Ir's senseless to argue that waves that cease to exist during the
process
of superposition have not interacted with each other, don't you think?

I don't have Born and Wolf with me at the moment but I seem
to recall that they said that any signal that was not single
frequency could not be 100% coherent. Presumably a signal
with modulation would be partially coherent.

Cecil,

It is easy to give examples where the waves survive the superposition, because they always do. It is rather strange that you are making this argument after all the back and forth about traveling waves and standing waves. Do we now have multiple flavors of EM waves? Some that obey superposition and some that don't?

I must have missed class the day they went over the theory of "cancellation". Is this another one of those convenient descriptions of results that you keep trying to remold into fundamental physical laws?

I stand 100% behind my two messages to Walt. If you actually read them you would note that I said for most cases it makes no difference whether the waves interfere forever or whether they interact and "cancel". As Owen pointed out a little while ago, we generally don't want to carry around lots of zero components in an analysis.

The bottom line is that EM waves do not interact in free space. Linearity and superposition could not hold if that were the case. Maxwell's equations would need to be recast.

There are exactly enough physical laws and principles now. There is no need to invent more on RRAA.

Source record: 43328

Hi,

I made the antenna out of a wood beam and 1/4" brass stock.
I used the QY4 program and the utilities program. Used some solid
18 gauge wire for the gamma match with a 4.7pf capacitor.
QY4 recommended 4.2pf. I used a small plastic box to house the
BNC connector, the gamma wire and the capacitor. Looks pretty
professional actually.
Well, I had set the program to optimize the antenna for 433Mhz
as that is what I was going to start with on my tracking transmitter.
Plugged the Yagi into my handheld, set the power to low, set the fwd
indication on my SWR meter and then did the ref reading. I was shocked
to see that it was 1:1.2. Set it up to 450Mhz and saw it was 1:1. For
this new ham, it was pretty surprising for a first project.
Will be using the antenna mainly to track an RDF beacon in an amateur
rocket. The link is here if your curious to see the unit. They make one
that transmits GPS data too. http://bigredbee.com/BeeLine.htm
Did some testing and I don't have as much directivity but I sure as
heck have plenty of gain with this setup. I might have to get a loop
if a model gets lost in some high weeds so I can get a better bearing
close-in.
I probably won't need an attenuator as I know the Foxhunt RDF folks
intentionally hide their transmitters in some weird places. Our rockets
most of the time land in an open area where our launchsite is.
Sometimes a high powered ship simply disappears off the pad and no one
sees it land. That's when the onboard RDF transmitter earns it's keep.
So far no one has lost a transmitter equipped rocket and there have
been several occasions where this has happened.
One person taped his transmitter to the shock cord that tethers the
pieces of the rocket under the parachute. He recovered his rocket,
brought it back and discovered no transmitter. They had been receiving a
signal all along but the model landed within sight. They went back out
into the field and found the still beeping transmitter with the loop
equipped receiver. Seems it was ripped off the shock cord and fell a
few thousand feet unharmed. This is where amateur rocketry can become
like an RDF foxhunt. :-)

Kurt,

Congratulations on your success.

Gain and directivity are related, Gain=Directivity/Loss, or in dB, Gain(dB)
=Directivity(dB)-Loss(dB).

So whilst it is possible to have gain without directivity (due to high
loss), the reverse doesn't happen.

> Best regards, Richard Harrison, KB5WZI

Richard, I couldn't find my Kraus book so I will have to let your
comment go.
I did look in the Jasik book on parasitic elements.
It said"A parrasitic element properly tuned will operate in phase-and-
field relationships
approximating those computed.In multi element arrays, independent
control and phase and amplitude is required and parasitics should be
avoided. However, they may be employed in antennas
designed primarily for power gain" To me this describes a yagi with
parasitic elements designed for power gain regardless of the mix of
polarisation. The Gauss system which does not use parasitics and

therefore pursues the independent control AND PHASE AND AMPLITUDE.
A yagi in a 90 degree multiple of earth does operate in a field
relationship because of its multi phase radiation where as the
gaussion tilts to remove unwanted phase and keeps only the required
phase. This is extremely important in cell transmittions since
channels are only of use when the polarisation is correct and any area
that does not comprise of the correct polarisation results in a
dropped call.
In my last post I mentioned the slope between scanning lines on a T.V.
as a reference line for true polarity. Any comment with respect to the
veracity of that statement since I see a direct corrorally between
that and radiation tilt angles?
Best regards
Art

All,

This question is: How can the ground system for a vertical be improved?

The RF ground calculates to about 52 Ohms. It consists of 16 radials varying in length from 24 to 45 feet. Four are buried and 12 are on ground. The location is the Pacific Northwest part way up a hillside. The surface is grass, the subsurface is clay. The value varies a little with rain, it has measured as low as 46 to 48 Ohms.

Just as additional information, the antenna is a loaded vertical, overall about 4 meters. The coil is about 35% from the base. The antenna is raised about 1 meter. I am aware the configuration is not optimum and a top hat would help, those changes will be made independently.

Several articles indicate this radial system should yield well under 20 Ohms, some estimates are under 8 Ohms. At this point my first target is under 20 Ohms. Little that I do seems to affect it. My question is:

What am I missing?

The problem is the value does not appear to change very much. I started with 4 radials and have been adding them periodically. Those changes do not seem to have a measurable effect. (However I must admit that earlier numbers not as good as the current measurement. I believe the current measurements are better then 10%.)

Thanks - Dan

Dan,

You refer to calculation of ground resistance and later to measurements.
It would help if you explained what you measured, the frequency of
measurement, and how you measured it, then how you calculated your
results.

Perhaps the regimen of that might help you to an answer.

Owen

They all obey superposition which can occur with or
without interference. And you are wrong about all
waves surviving superposition. Canceled waves do
not survive wave cancellation in the direction that
they are traveling. Access this web page and set
the two waves to equal frequencies, equal magnitudes,
and opposite phases, i.e. 0 and 180 degrees.

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

When you do that, the waves are canceled in their
original direction of travel. The energy in those
canceled waves certainly survives, but those two
original waves cease to exist never to be seen
again.

> I must have missed class the day they went over the theory of
> "cancellation".

You must have. Please run the above java application
and alleviate your ignorance about what you missed. Why
do the waves disappear when they are of equal magnitude
and opposite phase?

> I stand 100% behind my two messages to Walt. If you actually read them
> you would note that I said for most cases it makes no difference whether
> the waves interfere forever or whether they interact and "cancel".

Of course it makes all the difference in the world. That's
what the entire argument is all about. You simply cannot
sweep the truth under the "does not matter" rug. And until
you can say "all cases" instead of "most cases" your
argument is irrelevant. If it doesn't work for all, it
doesn't work at all.

> The bottom line is that EM waves do not interact in free space.

It is indeed difficult to get two beams of light collinear
in space space. But it is not difficult at all to get two

RF waves collinear in a transmission line. It happens every
time someone adjusts his antenna tuner for a Z0-match.

The IEEE Dictionary has an interesting definition for
"degree of coherence". Imax means intensity maximum
and Imin means intensity minimum.

Visibility = (Imax-Imin)/(Imax+Imin)

Light is considered "highly coherent" when Visibility
exceeds 0.88 and "partially coherent" when Visibility
is less than 0.88. Incoherent for "very small values"
of Visibility.

Kurt wrote:

Well, I had set the program to optimize the antenna for 433Mhz
as that is what I was going to start with on my tracking transmitter.
Plugged the Yagi into my handheld, set the power to low, set the fwd
indication on my SWR meter and then did the ref reading. I was shocked
to see that it was 1:1.2. Set it up to 450Mhz and saw it was 1:1. For
this new ham, it was pretty surprising for a first project.

This is exactly why I never trusted gamma matches on 70 cm. I consistently
got nearly perfectly flat matches all the way across the band using a gamma
match. This usally something aint right. and the antenna is probably
radiating more in the infra-red region than at the desire frequency. No
doubt there are others more skilled than I who can make it work For me the
quagi has worked to damned well for me to bother.

Jimmie.

Thanks Irv, now you tell me about the baking pan :-)
I now have it working. When I opened the controller, I first noticed a radio
shack
transformer that cost $1.98, pretty old, it would probably cost $9.00 now. I
assumed
it must have worked with the transformer at some point. Then I noticed the
full scale
trimpot was a pot/switch combo with the switch part inoperative. But both of
these
where doing what they should do though, so I continued and found a wire
connected where
it shouldn't be. I cut that wire and made the connection to the proper wire.
The unit works fine.
I thought I'd check the lubrication before I installed the rotor. Two hours
later, after picking
up ball bearings, learning how to get the bell properly aligned with the
wiper driver, getting
the ring gear aligned right, etc. The lube was good.
Well, I now know more about controllers and rotors than I did yesterday.
Thanks, Mike

Perhaps you should actually make an effort to explain why you see the relationships you see. I can think of no reason why anyone should be expected to go into great detail to explain your fallacies while you use almost no effort to explain why you think you are right.

This is good; a continuum with high coherence at one end, low
coherence at the other and medium in the middle, and, of course,
since the ends are infinitely small, no such thing as perfect
coherence or "NO" coherence (at least in the real world).

This then takes us back to the original point; there is always
some interference, though it may be small enough that an
engineer does not find it of interest.

Jimmie
As I said earlier the crt picture was in a Terman book. The picture showed a series of scan lines across the screen at a slight angle. Drawn at right angles to the sloping lines was a square i.e. bisected by the scan line. It was stated that the square represented aperture. Thus both the scan line and the aperture was tilted away from 90 degrees to the earth.
As I said earlier for purity of polarization a vertical dipole would have to be tilted approx 3 degrees. All this is a repeat of my last post which I consider an effort to rebutt what you call a "fallacy". I see similarities with what I stated earlier with respect to antennas. I never said I was correct to compare these analogies, I just put them forward for thought knowing that when the sets are assembled they are positioned to the north with the crt in a fixed position and the yoke is then manipulated to its best angle tho it has been known for T.V. pictures to be skewed by 3 degrees or so. Yup, I did make some effort don't you think?

> such that the horizontal vecot
> Jimmie- Hide quoted text -
>
> - Show quoted text -

I think I will try one more time with respect to tilt angle.
ARRL publications suggest that a vertical dipole only radiates a
vertically polarized radiation
Amatures read these publication and follow suit on their thinking, if
they can think that is,anything else must be wrong.
Well Jimmie you must surely know that only one electron stream travels
at the same angle as the dipole, any thing else does not. Therefore
the resultant vector angle cannot be parallel to the radiating member
and thus will radiate some horizontal radiation. To remove vertical
radiation you must tip the vertical dipole until the horizontal vector
is removed. All very simple.
Still to difficult for you? Well try this. Use your antenna program to
determine the horizontal
radiation and vertical radiation of a vertical dipole. Now model a
tipped dipole until the horizontal radiation is removed leaving only
vertical radiation and "Bingo" you should now understand and possibly
other amateurs will now question what they read in books. Tho I doubt

that since learners seem to only to be able to regurgitate rather than activate their brain.
If you are still not comfortable read Maxwells laws and activate your own brain and follow the leads given. There is no way I can activate your brain or any of the pseudo experts brains on line.

[snip]

Cecil,

That's really funny. A grad student and a programmer put together a simply java applet to try to illustrate the concept of interference, and you treat it as a new bible. I bet the authors would be appalled by your interpretation.

By the way, did you look beyond the pretty pictures and read the section where the authors said,

"All of the wave examples presented in Figure 1 portray waves propagating in the same direction, but in many cases, light waves traveling in different directions can briefly meet and undergo interference. After the waves have passed each other, however, they will resume their original course, having the same amplitude, wavelength, and phase that they had before meeting."

Hmmm, I think that is exactly what I said in this thread on RRAA.

But remember that definition is for fiber optics
sources, not amateur radio sources. Coherency
in amateur radio systems can get as close as
a zero reading on a reflected power meter.

Still there are those nagging assertions of Born
and Wolf that for two equal magnitude signals,
the total intensity possible for incoherent
signals is double the intensity of one signal.
The total intensity possible for coherent
signals is four times the intensity of one
signal.

One more example of an ignorant person making fun of something
he doesn't understand. One of those signals is s11(a1). The
other is s12(a2). Added together they equal zero. That's the
S-Parameter equation for reflections toward the source.

b1 = s11(a1) + s12(a2) = 0

If s11, a1, s12, and a2 are all not zero, the above equation
describes wave cancellation, something you say never happens.

> By the way, did you look beyond the pretty pictures and read the section

> traveling in different directions can briefly meet and undergo
> interference. After the waves have passed each other, however, they will
> resume their original course, having the same amplitude, wavelength, and
> phase that they had before meeting."

Yes, that happens "in many cases" but NOT IN ALL CASES. You
apparently missed the point which is the part where they said:

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not
actually annihilated, ... All of the photon energy present in
these waves must somehow be recovered or redistributed in a
new direction, according to the law of energy conservation ...
Instead, upon meeting, the photons are redistributed to regions
that permit constructive interference, so the effect should be
considered as a redistribution of light waves and photon energy
rather than the spontaneous construction or destruction of light."

> Hmmm, I think that is exactly what I said in this thread on RRAA.

No, what you have said on RRAA is that wave cancellation never
happens because wave cancellation doesn't occur in many
cases. That is obviously faulty logic and all it takes to prove
you wrong is one case of wave cancellation. That case happens
every time a ham adjusts his antenna tuner for zero reflected
power. If we consider the java ap as the reflected waves flowing

toward the source, setting them to 0 and 180 degrees is exactly
what happens at the antenna tuner.

Source record: 43346

Owen,

I did not want to concentrate on that; however it is a fair question.
The frequency is 3970 kc and the methodology is based on use of an hp
network analyzer. The analyzer has both polar and Cartesian displays.
The outputs were cross checked.f
The feed line was calibrated using a 25 Ohm termination to 180
degrees. The return measured about -9.4db (close to what is predicted
with line loss). This was checked against an open circuit confirmed the
calibration by a reading 1 degree and 1db. (very close to what is
predicted)

For the actual measurement the return loss was measured at just over
-26db at 0 degrees. (no feed-point network) Three models were used to
calculate the input resistance of the antenna. They all predicted an
antenna resistance of about 3 to 4 Ohms. (the suggested input network is
120 pf)

To focus on the question is: Why is the ground resistance so high? It is
not important at this stage to determine its precise value. The point is
it is high enough to cause a return of 0 degrees. This puts the 'system'
at over 50 degrees. Even if the antenna were 6 to 8 Ohms the ground loss
would be at least 42 to 44 Ohms.

I have read Maxwells laws and are familar with them, I have been since high school and nothing in them indcates what you say is feasable.

My antenna program indicates that all of the signal in a vertically mounted antenna is vertically polarized. I have racked my mind to see how you could come up with another conclusion and must assume you are confusing take off angle with polarization.

How do you get the idea that only one electron stream flows vertcally, obviously your understanding of how electrons flow in a conductor is flawed. The part of their movement that is responsible for current flow is more of a vibration than a flow, definately not forming streams. Since your theory is based on these misaligned streams which dont exist then your theory does not exist either.

If we assume your understanding of electron flow is correct then there will be a very huge number of of streams traving at various angles the length of the antenna. If the radiator is sufficentlyly small in cross sectional area this angle will be limited to a being very small angle, we will asume your three degees, much smaller is more realistic. Now to maitain an omni pattern wich direction due you propose to tilt it. If yor theory has any validity at all at best you will correct it in just one direction fora relatively small number of streams and make it worse in all others.

Again assuming there is some validity to what you say the polarization of an antenna mounted vertically to the earth at point a will have exactly the same polarity as one mounted somewhere else at point B reguardless of what you believe is the final polarity of these antennas they will be identical and this identicalness of polarity is the best arrangement for two antennas transmitting and receiving one anothers signal.

Hi Owen

I wonder if I misunderstand. I would think there could alot of
directivity in an antenna pattern but the system could have minimal gain due
to losses.

I think a summary is that at 3970KHz, the feedpoint Z looks like about 45 +j0 and you reckon the radiation resistance should be around 4+j0, suggesting the earth system contributes around 40 ohms of resistance. Observations at a single frequency provide a limited view of what might be happening.

Elevated radials should exhibit a clear resonance, and will offer the lowest impedance at resonance.

Buried radials will not exhibit such a clear resonance in lossy soil, and using your wire to form more short radials might give better performance than few longer radials.

Radials lying on the ground are likely to be somewhere in between. You may observe resonance, and in that case the ground system impedance will be optimised by "tuning" those radials (which will probably be a good bit shorter than formula length for free space radials).

Hi Dan,

Focus on Why? Why? This is something that you have absolutely no
control over without a huge investment in new dirt several 10s of
meter deep out to at least as far as the antenna is tall.

You want less resistance? then dig a hole and fill it with quartz
sand. Build a dune to drive the loss down further.

A suitable substitute is to lay out a ground field (radial wires). The
more the better. Here is the Why? you should be asking (Why more
wires?).

The path through the earth is shortened between adjacent ground wires.
Less path, less loss. The earth current travels not IN toward the
center as the radials do. The earth current travels ACROSS or
circumferentially towards the radial wires. This is due to the phase
lag between the induced earth current and the radial current. The
greater the distance between radials, the more path loss from the
average distance between the radials, to the radials.

As this is very difficult to treat in words alone, it is undoubtedly
confusing in the description above.

I'd vowed that I wouldn't hit this tarbaby yet again. But here I go.

Among the junk science being bandied about here is the following supposition:

Suppose you have beams from two identical coherent lasers which, by a system of (presumably partially reflective and partially transmissive) mirrors, are made to shine in exactly the same direction from the same point (which I'll call the "summing point"). Further, suppose that the paths from the two lasers to this summing point differ by an odd number of half wavelengths. So beyond the summing point, where the laser beams exactly overlie each other, there is no beam because the two exactly cancel. Or, in other words, the sum of the two superposed fields is zero. The recurring argument is that because each laser is producing energy and yet there is no net field and therefore no energy in the summed beams, something strange has happened at the summing point (or "virtual short circuit"), and creative explanations are necessary to account for the "missing energy". One such proposed explanation is that the mere meeting of the two beams is the cause of some kind of a reflection of energy, and that each wave somehow detects and interacts with the other.

Well, here's what I think. I think that no one will be able to draw a diagram of such a summing system which doesn't also produce, due solely to the reflection and transmission of the mirrors, a beam or beams containing exactly the amount of energy "missing" from the summed beam. No interaction(*) of the two beams at or beyond the summing point is necessary to account for the "missing" energy -- you'll find it all at other places in the system. Just as you do in a phased antenna array, where the regions of cancelled field are always accompanied by complementary regions of reinforced field. Somewhere, in some bounce from a mirror or pass through it, the beams will end up reinforcing each other is some other direction. My challenge is this: Sketch a system which will produce this summation of out-of-phase beams, showing the reflectivity and transmissivity of each mirror, and showing the beams and their phases going in all directions from the interactions from each mirror. Then show that simple interaction of the beams with the mirrors is insufficient to account for the final distribution of energy.

Next, do the same for a transmission line. Show how two coherent traveling waves can be produced which will propagate together in the same direction but out of phase with each other, resulting in a net zero field at all points beyond some summing point. But also calculate the field from waves reflected at the summing point and elsewhere in the system due to simple impedance changes. Show that this simple analysis,

assuming no interaction between the traveling waves, is insufficient to account for all the energy. A single case will do.

Until someone is able to do this, I'll stand firm with the unanimous findings of countless mathematical and practical analyses which show superposition of and no interaction between waves or fields in a linear medium.

(*) By "interaction" I mean that one beam or wave has an effect on the other, altering it in some way -- for example, causing it to change amplitude, phase, orientation, or direction. I'm not including superposition, that is the fact that the net field of the two waves is the sum of the two, in the meaning of "interaction".

One more example of an ignorant person making fun of
things he doesn't understand. The principle of the
conservation of energy indeed states that energy is
not gained or lost - it just gets shuffled around.
When EM wave cancellation occurs, the energy remains
in EM wave form and simply gets redistributed.

As we tune our antenna tuners while watching the
reflected power indication, we are varying the
magnitude and phase of the two component reflected
waves at the tuner input. When those two component
waves are adjusted to equal magnitudes and opposite
phase, reflections toward the source are obviously
canceled since they can be measured as going to zero
in the direction of the source. The following S-Parameter
equation describes the final outcome toward the source.

b1 = s11(a1) + s12(a2) = 0, total destructive interference

Since energy cannot be destroyed by an antenna tuner
and since there are only two directions available, in
a lossless system, the energy in waves canceled toward
the source must be redistributed (re-reflected) to waves
traveling toward the load as constructive interference.
That's the other S-Parameter equation.

b2 = s21(a1) + s22(a2) = Vfor/SQRT(Z0)

Square those equations and you get the power equations.
|b1|^2 = net reflected power = 0
|b2|^2 = net forward power = all the available power

It is a fairly common practice in broadcast designs to combine the outputs of two r-f amplifiers of equal power rating, using a 4-port, 3 dB coaxial hybrid. The two amplifiers are driven by a single exciter through a suitable splitter. The antenna connects to one output port of the hybrid, and the other output port is connected to a dummy load.

When the relative r-f phases of the two txs are suitably set, the antenna connection of the hybrid receives the total output power of the two txs, and the dummy load port receives zero. When the relative r-f phases of the txs are changed by 90 degrees from that setting, then the conditions at the output ports are reversed.

The total average power available at the hybrid output for both of these conditions is twice that of a single tx without the hybrid.

Does the quote from Born and Wolf support this?

My suggestion would be a log periodic. I have a Tennadyne, 6 el log,
http://www.tennadyne.com/ and it works very well for me. The nice part
is the ability to go anywhere on the bands with a good usable SWR and
consistent performance. If I had to do it over again, I would buy the 8
el Tennadyne as the SWR curves are a bit flatter. It&#65533;s been up for about
6 years now and has weathered ice storms and high winds with no problems.
I like the Tennadyne brand and I think they are honest about their
antennas.

Roy, it is done all the time represented by the
S-Parameter equation for the reflected wave
toward the source. Assuming an impedance discontinuity
in a transmission line:

b1 = s11(a1) + s12(a2) = 0

If b1=0, then s11(a1) and s12(a2) are indeed two coherent
traveling waves propagating together in the same direction
but out of phase with each other. The net reflected wave
field is zero.

I would just use normal 500v silver mica capacitors in series if necessary. At the 100 watt level the capacitors in a trap don't have to work too hard. Silver micas have good RF performance and easy to come by. If you use EZNEC to model your antenna it can tell you the voltage across your traps at your max power level making it easy to pick out your capacitors. You can down load a trial version that can easily model your antenna.

Cecil,

Sorry, I simply cannot keep up with you. We seem to be switching from RF to optics in order to explain something or other, and now we are switching from optics to S-parameters to explain the explanation.

You accuse me of saying that waves never "cancel", right after I told you that "cancel" is not a good description in detailed technical analysis. Do you actually read anything here?

Going back to your oft-stated line about Galileo, you seem to be on the other side now. You keep insisting on a Cecil-centric universe, with the consequent requirement to add more and more crystalline spheres to explain all of your "creative" ideas.

Stick to the basic EM understanding that has stood for more than 100 years. No need to keep inventing new principles. The old ones work just fine.

(You must be getting desperate; the ad hominem attacks have started.) 8-)

> Does the quote from Born and Wolf support this?

Yes, there is obviously no interference between the
two transmitters if the powers simply add together.
You have doubled the current capability without
doubling the voltage capability - that's not
interference.

For interference to occur, both the E-fields and
the H-fields must be superposed at the same time
such that both fields increase or decrease by the
same percentage. So how do we double the voltage
and double the current in the 50 ohm transmission
line to the antenna?

Put a transformer on the output of each transmitter.
Wire the secondaries in series. We have doubled the
voltage output. Now drive the 50 ohm load with that
doubled voltage and see what happens. This is equivalent
to constructive interference. Hope you are running
the transmitters at half power. :-)

So are you saying the physics concepts from the field
of optics are wrong? Are you saying the S-Parameter
equations are invalid? If not, seems you are having
a hard time defending your concepts against those
valid concepts. That should tell you something about
your (simplified short cut) concepts.

I'm going to keep it up until you give up on the notion
that you already know everything and therefore reality
obeys your every whim. You cannot dismiss wave cancellation
simply because you find that part of reality distasteful.

In analyzing an impedance
discontinuity in a transmission line, the S-Parameter
equations are accepted as valid. b1 is the normalized
reflected voltage toward the source.

b1 = s11(a1) + s12(a2) = 0

When b1 is zero, waves s11(a1) and s12(a2) have been
canceled because they are of equal magnitude and opposite
phase. Simple cause and effect - not rocket science.

If you can prove those concepts from the field of optics
are invalid and that an S-Parameter analysis is invalid,
now would be the time.

> You accuse me of saying that waves never "cancel", right after I told
> you that "cancel" is not a good description in detailed technical
> analysis. Do you actually read anything here?

Wave cancellation occurs all the time, Gene. Every time
a ham tunes his antenna tuner for zero reflected power,
he has caused two reflected waves to cancel. I am amazed
at how many otherwise intelligent posters to this newsgroup
attempt to engage in the copout of sweeping under the rug
anything that they do not understand and/or don't want to
deal with.

> Stick to the basic EM understanding that has stood for more than 100
> years.

That's exactly what I am doing. You seem to be relatively ignorant of those century old concepts. I don't know when interference was first explained but it was long before you and I were born. I am repeating principles that have been around for a century including the wave reflection model.

What has actually happened is that seductive short cuts have left many ignorant of the basic principles, e.g. Standing waves can exist without reverse traveling waves. Reverse traveling waves exist without a source of energy. Waves never interact. etc. etc. etc.

Simple answer- add more radials. Especially if the impedance is varying noticeably depending on ground moisture, you need more radials.

Another possibility is that if there is some other conductor in the near field (tower, house, other wires, etc), the impedance might not be what you expect.

How is the antenna loaded and what is the Q of the loading coil? Coil
losses are almost certainly 5 ohms and could easily be as high as 35 ohms.

I take this to mean that with largely incoherent sources
the intensity is doubled everywhere.

With largely coherent sources, the average intensity is
doubled everywhere, but there is also a spatial distribution
where the peak intensity is 4 times, but the minimum is zero
(thus the same average of two).

Except that Richard's description sure seems to meet the
requirements of coherency. Can you offer a way for use
to know whether two signals are coherent?

Secondly, I am at a complete loss to understand how you
can be arguing that when two signals of a particular
power interfere, the result is 4 times the power. This
sure seems like you're getting something from nothing.

What happened to the staunch acceptance of 'conservation of
energy'?

Being a little more precise:
With mutually incoherent equal-magnitude sources,
the maximum possible peak intensity is double the
intensity of a single wave. There's no interference.

For "largely incoherent sources", the peak intensity
would be slightly more than double.

> With largely coherent sources, the average intensity is
> doubled everywhere, but there is also a spatial distribution
> where the peak intensity is 4 times, but the minimum is zero
> (thus the same average of two).

With mutually coherent equal-magnitude sources,
the maximum possible peak intensity is four times
the intensity of a single wave, i.e. there is total
constructive interference. (This can happen
at a Z0-match in an RF transmission line.)

For "largely coherent sources" the peak intensity
would be slightly less than four times.

Thanks for doing so.

The junk science is often presented with very rational sounding
arguments and it can be difficult to detect the flaws. This example
was a case for me and you expose the flaw nicely.

What I have difficulty with is deciding on the value of the junk
science. On the one hand it misleads many; on the other, debunking
provides opportunity to develop deeper understanding.

When I first started lurking on this group many, many years ago,
I didn't even know that there was a question about "where does the
reflected power go". Following the debates and iterating to the
correct answers has been extremely educational, much more so than
just accepting the correct explanations without question.

The promoters of junk science fulfill an important role in this
process and I can't decide if their net effect is good or bad.
The bad effects are, of course, when they successfully lead
others astray.

On the whole, good or bad? I haven't decided.

BUT, the two equal-power signals in my scenario are exactly coherent at the output port where they combine to produce twice average output power of either tx.

Please explain, in light of your concepts?

If we can cause them to interfere, that is proof that
they are coherent. If their reflected waves superpose
with destructive or constructive interference present,
then they are coherent.

> Secondly, I am at a complete loss to understand how you
> can be arguing that when two signals of a particular
> power interfere, the result is 4 times the power. This
> sure seems like you're getting something from nothing.

Maybe it seems that way to you but it's because of
confusion. If the intensity of each of two coherent
waves is one watt/unit-area and total destructive
interference occurs at one point, two watts/unit-area
have seemingly disappeared. Since energy cannot disappear,
those two watts/unit-area must appear as constructive
interference somewhere else. If total constructive
interference appears somewhere else, the total intensity
is one watt/unit-area from the first wave, one watt/unit-area
from the second wave, plus the two watts/unit-area from
the total destructive interference. Adding all those
intensities up gives us four watts/unit-area at the point
of total constructive interference. The intensity at
the total destructive interference point plus the
intensity at the total constructive interference point
still averages out to two watts/unit-area, exactly the
intensities in the original waves and exactly what it
takes to satisfy the conservation of energy principle.

Your "something for nothing" doesn't exist. In the absence
of a local source, any constructive interference must be
offset by an equal magnitude of destructive interference.

You have about enough audio power to plate modulate a 25 watt input amp.
Maybe something using a 2E26 or a 6DQ6 tube.

As Cecil mentioned you may want to modulate the screen of a pair of 6146
tubes or similar to get enough power out to make it worthwhile.

"The Gauss system, which does not use parasitics and therefore pursues the independent control AND PHASE AND AMPLITUDE."

Parasitic arrays can also use independent control of phase and amplitude, I worked with curtain antenna arrays in the 1950`s used for shortwave broadcasting.

The array consisted of (4) 1/2-wave dipoles, 2 over 2 all in the same plane, separated vertically by a 1/2 wavelength and suspended over the earth by a gap of 1/2-wavelength. An identical dipole array was suspended immediately behind the driven dipoles. It served as a parasitic reflector.

The harness connected to the parasitic array was identical to that connected to the driven elements except that instead of being connected to the transmitter, it was connected to tuning stubs. We used an RCA WM 30A broadcast phase monitor with sampling loops suspended on driven and parasitic elements to adjust phasing of the reflector.

> of either tx.
>
> Please explain, in light of your concepts?

I thought I did. You have combined those outputs
without producing any interference. If there is
no interference, as far as power goes, it doesn't
matter if they are coherent or not.

Assuming P1 is the power output of the first
transmitter and P2 is the power output of the
second transmitter, if Ptotal = P1 + P2 + 0,
the interference (last) term is obviously zero,
i.e. it's prima facie - no interference.

If you double the H-field (current) while keeping
the E-field (voltage) constant, you have not
produced any interference.

If you double the E-field (voltage) while keeping
the H-field (current) constant, you have not
produced any interference.

If you double both the E-field (voltage) and the
H-field (current) at the same time, you have produced
total constructive interference.

If you zero both the E-field (voltage) and the
H-field (current) at the same time, you have produced
total destructive interference.

For interference to exist, both the E-field and
H-field must be changed by the same percentage
thus keeping their Z0 ratio constant.

If both fields decrease, extra energy is available
during that destructive interference event. If both

fields increase, extra energy is required by that
constructive interference event. In the absence
of a local source, |destructive interference| must
always equal |constructive interference|.

Hint to omniscient gurus: One cannot use ignorance
for exposing flaws. Roy says in his Food for Thought
article:

> > I personally don't have a compulsion to understand where this power "goes".

Seemingly, that feeling of his is supposed to be enough
incentive to discourage the rest of us to give up on our
quest for tracking the energy through the system.

Roy has ploinked me for disagreeing with him. What
does that say about his inability to technically
defend his concepts?

The S-Parameter equations completely debunk what Roy
posted.

b1 = s11(a1) + s12(a2) = 0

|b1|^2, the reflected power, equals zero because
of wave cancellation involving those components
of a1 (forward normalized voltage) and a2 (reflected
normalized voltage).

If s11, a1, s12, and a2 are all non-zero, then wave
cancellation has occurred between s11(a1) and s12(a2)
proving Roy's statements to be false. The above wave
cancellation happens every time a ham adjusts his
antenna tuner for zero reflected power.

Art wrote:
"The picture showed a seies of scan lnes across the screen at a slight angle."

Yes. I think that is right but I learned about TV back in 1948 and haven`t thought about it much since. As I recall, the designers of the U.S. TV system decided to construct a picture consisting of two interlaced fields. The first starts at the center of the screen at the very top of the picture, sweeping to the right on a slight downward slope, then retracing quickly to the lefthand edge of the picture. There the next parallel but slightly lower line of field or frame starts being written.

As I see it, the tilt or slope is strictly an arbitrary decision of the designer but conformity is required of the standard to work within the original system.

>insulation or corrosion due to buried radials?

Not much, practically; unless the wire is extremely thin, and the
currents are large. Loss is in the earth. You can, of course, build
a very crummy radial system if you try hard. For instance, using
expensive piano wire in place of cheap house wiring.

Keep in mind that EZNEC reports the RMS voltage, while capacitors are rated for peak voltage. So multiply the EZNEC values by 1.41 to get the required capacitor rating. Then add whatever additional safety margin you think is appropriate.

I presume you mean 160 KHz, not MHz.

Almost any of the N channel power FETs intended for switching power supply use will work at 160 KHz.. Forget about the 12W amp; you would need a low impedance modulation transformer for that. I would start with a non regulated power supply at about 30 volts, and run that to a buck regulator. Set the quiescent voltage to 12 V. Now, AC couple the audio (a few milliwatts) into the regulator reference input, and adjust the audio amplitude so that the regulator output swings between 0 and 24V. That is the supply for the power FET.

To operate in class C, you will want to drive the gate with a rectangular waveform. I would start with about 25% duty cycle. There will be a tuned circuit at the output of the FET; that has to have a fairly low loaded Q, or you will cut off the sidebands.

Actually, It should be possible to do this without even having a separate RF amplifier. Run the buck regulator at 160 KHz with almost no filtering at the output. The regulator output will be AM modulated 160 KHz. Filter it in an LPF.

If you meant 160 MHz, the first paragraph still applies. Use the regulator output to power an RF transistor operating at 160 MHz.

There is no problem with that for shortwave broadcasts since not only
are you looking for a broard arrival area you are also looking at a
skip distance wheret different polarization arrives at the same
polarity.
If it were a Gauss form it would be of a higher
power but a much smaller arrival area which means a smaller audience.
Though I must add that a Gaussian arrival area can be tailor made
rather than the narrow lobe associated with other radiators.
It is when " boresight" is of a concern that such arrays fall in
disfavor,
as in cell phone work and satellite work where one should take note
of maximum polarization purity. Tho' why satelites still use
turnstiles
is beyond me since only one polarization is required but I am sure
there must be a reason, possibly because there is not an overpowering
need of multi monitoring communication channels.

My experience seems to be that the performance of NVIS dipoles (at or under around 30 feet high for 80 meters) doesn't noticeably change with orientation. In other words ... and despite what modeling programs say ... BVIS dipoles are pretty much omnidirectional.

I haven't scientifically tested that but it does seem to me that since most NVIS radiation goes approximately straight up (definition of NVIS), it really shouldn't matter much how the antenna is oriented.

Have you all found that to be true, or false?

If I do want near-omnidirectional performance, in the real world (versus in a software program's modeling), am I better off with an inverted vee that's up 30 feet in the center, vs a dipole that's 30 feet up along its full length?

How about an inverted vee that's up 50 feet in the center and 10 feet at the ends, versus a dipole that's 30 feet up along its full length?

Thanks for the info Jimmie. I gotta find a 70cm repeater in a
reasonable range and see if I can get some signal reports. As
mentioned, I was tentatively going to use this for RDF so in actuality
I could just connect it to a handheld scanner. I was told though if an
antenna demonstrated a good SWR on transmitting it should be good for
receiving. Sounds like that may not be the truth though judging by your
experience.

Called discarding the baby with the bath water. Such is the fate of observed reality in the face of novel theories.

This specious argument (posing quadruple powers to confound expectations) demands the slight of hand rhetoric in that when clear minds consider the entire field of radiation is summed, then you get the average of reinforced energy and canceled energy which is:
2

This merely reinforces yet another observed (but rhetorically dismissed) reality:

With a 130 ft dipole at 30 feet, the azimuthal radiation
pattern at 60 degrees is 3 dB down off the ends of the
dipole. I have never seen the minimum NVIS angle
defined anywhere.

Hi All,

I would add that even if this safety factor is ignored (even at the
additional burden of ignoring the RMS to Peak conversion); that some
may feel their set up works fine, but is now off frequency. Mica caps
are said to be "self healing." That is accounted for the removal of
plate area (by the arc through) near the puncture. Net result of
overloading is neither a short nor an open.

You could test them with a Capacitance meter and find they still
exhibit capacitance, and perhaps not much D (but how many meters
actually measure D?).

The tilt of the horizontal scan lines is simply a consequence of the linear vertical deflection ramp being applied to the yoke at the same time as the horizontal deflection.

Roy Lewallen, W7EL

3981. What kind of 1/2 wave antenna is this?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-09 17:14:19 UTC
From: Rick <Nospam@reply.in.gp>
Message-ID: <pan.2007.04.09.17.14.18.339756@reply.in.gp>
Source record: 43296

Way back in the good old days, I had a situation where I couldn't center-feed an antenna, and couldn't use any kind of end-fed antenna that required a ground system. So, I built an antenna that's described below.

1/4 wavelength of wire going to two egg insulators. Off of one of the egg insulators is another 1/4 wavelength of rope. The feedline (coax) is taped to the rope along its length, then the rope and feedline combination is enclosed in 1/4 wavelength of copper braid. The center conductor of the feedline goes to the wire, and the shield goes to the braid.

This then becomes for all practical purposes a 1/2 wavelength end-fed, which is actually a center-fed because that's where the coax center conductor is actually connected. Unlike a traditional center-fed dipole, you don't need to worry about running the coax away at right angles for a certain distance.

I seem to recall that this antenna worked pretty well on 20 meters but I really had nothing to compare it with, and I only ran 50 watts anyway so didn't get much DX.

I vaguely recall this antenna being referred to as a "bazooka" but I have since seen the term "bazooka" applied to something else (e.g. http://www.hamuniverse.com/bazooka.html), and mostly all I see is references to a "double bazooka" (is there a single bazooka?).

Does this ring any bells with any of you?

Where can I buy braid that will be suitable? Most braid I've seen is flat and if it can be rounded out at all (so that things can be inserted inside the braid), doing so over a 1/4 wavelength on 40 or 20 would be very difficult.

Thanks...

> expectations) demands the slight of hand rhetoric ...

Do you really think that Born and Wolf engage in
"slight of hand rhetoric"? Quoting them speaking
of the combined intensity of two equal magnitude
waves, I1 and I2.

"... and the intensity varies between a maximum
value Imax = 4*I1, and a minimum value Imin = 0
(Fig. 7.1)."

Fig. 7.1 is a sinusoid with a varying amplitude
from 0 to 4*I1 on the Y axis and relative phase
angle plotted on the X axis.

The average intensity is, of course, 2*I1 in
accordance with the conservation of energy
principle. Such is the nature of constructive
and destructive interference.

OK, except that it wouldn't be bent at the center... the 1/4 wave of wire
and the 1/4 wave of rope / coax / braid would all be horizontal.

Haven't considered any satellite attempts but I did try to pick up that spacesuit they tossed out of the ISS. Saw the ISS streaking across the sky, which was cool, but didn't hear anything on my scanner with a simple rubber duck. (Wonder why? sic) :-) That was before I was trying to study for a ticket.
I'll have to look into it. I suspect if I could hear the beacon I would be pointing in the right direction then call a CQ and see if I get a reply?

>>> detailed explanation of this circumferential current and its cause?
>>
>> Hi Roy,
>>
>> Brown, Lewis and Epstein.
>>
>Which page?

Hi Roy,

It is distributed through the discussion.

Pg. 757 (at the top of the page introduces):
"These losses are due to conduction of earth
currents through a high resistance earth..."

"Where there are radial ground wires present,
the earth current consists of two components,
part of which flows in the earth itself and
the remainder of which flows in the buried wires."

"...all the various components differ in phase."

This establishes the relationship and distinction in the various
currents. It is the current in the earth that is the topic of
discussion here. That current is out of phase with respect to the
currents (at the same radial distance) found in the buried wires. No
wires, no phase issue. No phase issue, and earth currents would be
radial. Now, to distinguish this from circumferential is not to say
this is absolute (it does not follow an arc of constant radius).

This is extended to coverage at the bottom of page 758:
"The actual earth current and the current flowing in the
radial wires are given...." [formula shown in the original]

"From (8) [that formula] we see that the earth
current proper leads the current in the wires
by 90 electrical degrees."

At a radius, the earth phase and the wire phase exhibit a potential
difference which results in conduction that is not strictly radial
(the term circumferential through the combination of vectors might be
replaced with spiral, or diagonal). The earth's resistance comes into
play at page 760:
"When the earth is of good conductivity [a paradox ensues],
the current leaves the wires and enters the earth closer to
the antenna than it does when the earth is a poor conductor."
and hence the advice for replacing dirt with sand OR providing more
closely spaced radials, closer in.

"Thus the regions of high current density are subjected
to still more current with higher losses in these regions."

I think we both understand that light travels at a velocity which is dependent on the medium through which it is travelling. You seem to want to continue to argue about that, and to tell you the truth I can't see much difference between that, and the kind of debate going on over and over in this newsgroup.

I saw that as analagous to a horizontal beam i.e current with magnetic
electrons at right angles
in a time varying field, the resultant vector being at an angle with
respect to the horizontal sweepof the deflection signal. Either way,
since all vectors do not move in the same direction
the resultant vector cannot align with any existing vector.In this
case it presents an oportunity for the designer to have maximum
brilliance together with ramp. Who says you can't have your cake and
eat it to!

If this fact is beyound you as you say then you have no business lecturing other people on antenna theory and that you are as brainless as you claim others to be. They are circularly polarized because satellites tumble in space resulting in there polarity constantly changing, also other reason why the polarity of an earth station would not match that of a satellite, look them up. This can be a real problem with a linear polarity antenna but no problem at all for a circular polarity antenna such as the turnstile.

Cecil,

It is interesting that you rarely address the technical points that I make. It is usually something along the lines of the above throwaway comments.

What are you trying to hide?

I am still waiting to learn the technical details of "cancellation", including the proper units and the characteristic equations. There has been deafening silence in response to my similar query about "interference".

I have been called lots of things in my life, mostly deserved, but rarely have I been called ignorant. It is obvious that this thread has long outlived any chance for a meaningful discussion.

You win! Keep on building more spheres.

The quote from Born and Wolf that Cecil cites supports the 'profound'
notion that (E1 + E2)^2 / (E1 + E2) = 4.

I have posted the details of cancellation more than
once and you haven't disagreed except in an ad
hominem way with zero technical content.

Once again here is the S-Parameter equation for
the reflected wave at a Z0-match impedance
discontinuity in a transmission line:

b1 = s11(a1) + s12(a2) = 0

b1 is the normalized reflected voltage at the
Z0-match. |b1|^2 is the reflected power in
the direction of the source.

s11(a1) is the normalized external reflected
voltage at the Z0-match.

s12(a2) is the normalized internal reflected
voltage making it through the Z0-match back
from the mismatched load.

Since b1 = 0, s11(a1) and s12(a2) have canceled.
s11(a1) and s12(a2) are of equal magnitudes and
opposite phases. Those waves are canceled toward
the source. Their combined energy components join
the forward wave toward the load.

Wave cancellation is what happens when a ham tunes
his antenna tuner for zero reflected power. I dare
say you have engaged in that very behavior leading
up to wave cancellation of reflections in the
direction of the source.

Jimmie, think before you post. A turnstile is not perfectly CP. For perfection changes are needed but as I said earlier perfection may not be necessarily desired. If you are going to disagree with everything you may want to be more choosey in your selection of posts plus reading the content more than twice before you decide to expose your lack of knoweledge.

4000. Re: high earth resistance

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-09 19:12:32 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <131l41774927168@corp.supernews.com>
Source record: 43314

Richard,

I disagree with your conclusion that currents flow circumferentially. It does not say so in the paper, and I don't believe it can be inferred from what is said in the paper. If you were to draw a diagram showing the currents produced by the phase shift between earth and radial currents, you'd find that the net current resulting from this phase shift is purely radial, not circumferential.

If the currents flow circumferentially, do they flow clockwise or counterclockwise, and at what magnitude relative to the radial currents? Surely there's some reference which shows this calculation which you could direct me to or, if not, you could show how the calculation is done and what the result is.

The imperfection is only slight and works quite well for all pratical
purposes. You should be sure of your own knowledge. I f perfection was
required I doubt if anything would ever perform satisfactorly.

This isn't the first time I've failed to communicate, and I'm sure it won't be the last.

The sole point I was trying to make is that the letter c is just about universally used, as far as I can tell, to mean the velocity of light in a vacuum. That symbol is not generally used to mean the speed of light in any other medium.

There sure appears to be something wrong with that
equation, Jim. If E1 = E2 = 1 volt, then you have
4 / 2 = 4 which seems a bit wrong, if you don't
mind me saying so. What dimensions does your '4'
above have? Seems it would have to be 4 volts.

Assuming E1 = E2, I think what you meant to say was:

(E1 + E2)^2 / E1^2 = 4 (dimensionless)

which is what Born and Wolf say in equation (17)
chapter 7. Please note that is total constructive
interference as defined by Hecht in "Optics"

Also please note that if those signals are the opposite
phase:

(E1 - E2)^2 / E1^2 = 0

That's total destructive interference as defined
by Hecht.

I "know" it can be perfected, you however have "doubts" As I said
earlier read twice before you choose to disagree. You are
overestimating your antenna abilities and really should revert to a

learning mode. If it was baseball you would be long gone.

The last paragraph above is a perfect example of your tendancy to
misinterpret these texts, Cecil. Born and Wolf does not (and would
not) assert that there is "no effect" when mutually incoherent waves
are superposed. It's not reasonable to say that. There is certainly
an effect. In fact Walt and I use the effect whenever we tune our basses.

An illustration can be viewed at:

Hi Roy,

To insist that the paper be complete where the reader has the
competence to understand what is implied; well, that goes beyond
standard practice. Further, the implication is hardly momentous when
the force of the writing is in demonstrating (not finding) a solution
to loss. Their style is clearly descriptive, not pedantic.

One very simple observation drawn directly from the text
at page 760:
"When the earth is of good conductivity,
the current leaves the wires and enters the earth closer to
the antenna than it does when the earth is a poor conductor."

How is it THIS current is traveling radially, the same direction as
the wires, both leaving the wire (an orthogonal aspect) and yet moving
in the same direction. This is a contradiction to the geometry of the
description if we are to abide by your rejection of my
"interpretation."

Their (not my) statement, supported by their other text, hardly makes
sense otherwise. Current only flows along a potential gradient and
the phase shift between (by their own distinctions) wire and ground
constitutes such a gradient.

It is a vastly more speculative "interpretation" to suggest the
current leaves the wire to travel in the same direction and the
authors definitely don't say that, do they? Common sense would
dictate a fairer interpretation that conforms to phases and the
distinctions (separation of currents) they drew from them.

my recollection from optics is

c/c' = n, index of refraction for the c' medium, (c always used as the
constant in a vacuum).

> Roy Lewallen

I'm with Roy on this. v is a wonderful symbol for generalized
velocity; c is used by far too many--as Roy says, almost universally--
as the velocity of light in vacuum. Speaking of failures to
communicate, I think using a symbol that's so well accepted to mean
one thing when you mean something else is a wonderful way to
precipitate failures of communication. Clear communication is aided
by not changing the meaning of well-accepted symbols.

"Let's see... e=m*c^2. Now what c is that? Is it 3e8m/s, or is it
only 3.4e7m/s because I'm in water? Will the nuclear blast be only
1/78 as energetic because it's conducted in water? Oh, but wait, at
higher frequencies c is greater than at low frequencies, in water.
Oh, I'm getting soooo confused...." No, c=3e8m/s, nominally.

"Let's see... epsilon-zero = 1/(mu-zero * c^2). Now what c is
that? ...."

Examples of equations where c is taken for granted as the freespace
speed of light abound. I think publishing an equation where c is the
speed of light, but not necessarily the freespace speed, shows poor
technical editing.

Cheers,
Tom

So according to your theory I can take a 1 watt laser, split the beam into two coherent beams, recombine the beams in-phase together along the same path thus creating constructive interference, and obtain 2 watts of laser power. Or would it be 4 watts?

Dan,

I asked your for the details of your antenna and measurements, and how you did your calculations, but I am still left wondering how you have what appears to be a purely resistive feedpoint impedance and a radiation resistance of 4 ohms. The second implies a short vertical, and if that is the case, the first implies some form of loading... but you didn't mention loading of any kind. Loading, if you have used it, may introduce an equivalent series resistance at the feedpoint.

Once again, a dansawyer problems leaves us guessing to fill in the missing dots before attempting to joint them up to make a picture.

Often, solving a problem is about being able to draw the picture, once the picture is draw, the answer becomes trivial.

I think I know which one, and as far as I know there hasn't been a dispute about that on RRAA. The question posed on the newsgroup, and the one which still seems to be a point of contention is which one should go in *this* equation:

f = c / w

I maintain the answer is still - it depends on the medium.

I am sorry to have gotten so many pairs of panties wadded up about this. Seemed a noncontroversial notion to me at the time.

I don't know that modelling programs are in conflict with the the
observation that dipoles low over real ground are nearly omni directional
at high elevations.

>

I wrote an article on the design of an antenna for local contacts on 40m,
it is at http://www.vk1od.net/7MDipole/7MDipole.htm . It may be of
interest.

I think you are on the wrong tram about the modelled performance.

>
> How about an inverted vee that's up 50 feet in the center and 10 feet
at
> the ends, versus a dipole that's 30 feet up along its full length?
>

Mounting a half wave dipole low over real ground modifies the pattern
from the free space pattern, the the whole pattern is deformed by the
presence of the ground and nulls previously off the end are not nearly as
pronounced.

When you rig the dipole as an inverted V, the pattern is further deformed and the nulls are even less pronounced.

Ask yourself the question "is a dipole horizontal over ground (at any height) omni-directional at the zenith?". If you found a modelling program that, used properly, says otherwise, tell us about it.

NVIS isn't strictly about the zenith, but an antenna that is omni at the zenit, and doesn't have deep nulls (dipole low over real ground), is close to omni at high elevations. The exact variation will depend on frequency, mounting height, ground parameters, and leg angles if an inverted V. If you could rotate such a dipole, I would defy you to reliably measure the out-of-omni above 50 deg elevation with an S meter.

Jim, I am not a physicist... but I recall when introduced to e=m*c^2 at high school, that "c" was defined as "the velocity of light in a vacuum".

If the "in a vacuum" qualification was unnecessary, if wasn't relevant, I wonder why they complicated and restricted the definition?

I am with you (until someone presents a convincing argument otherwise).

This leaves all those books, software etc giving a value for "c" as not necessarily in need of revision.

I was also confused by the base of the antenna being 1 meter above
ground, and the radials lying on the ground, or buried. If the base
of the antenna is 1 meter high, then any connection to the radials
is part of the radiation system. Why would you feed the antenna
1 meter up, and not at the base? The antenna is therefore
a ground mounted 5 meter vertical.

NEC predicts an input impedance of 4 - j 1300 with 36 ten meter
radials 1" below an average ground. Loading coils will of course
add to the input impedance.

The measured data are suspect. It would be interesting to know
the length, and type, of coax connecting to the network analyzer.
The return loss of 25 ohms at the end of a piece of coax will be
> 9.5 dB. Unless the coax is cut to a precise known length it
is unlikely that the phase angle of the return loss will be zero.

Frank.

If it were total constructive interference, two 1/2W
beams would yield an intensity of 2 watts. Of course,
at another location, total destructive interference
would have to occur where the intensity was zero.

Put another way, the bright interference rings would
contain two watts per unit area while the flat black
rings would contain zero watts per unit area thus
averaging out to the original total of one watt.

As I said before, this ain't rocket science.

I've always gotten the point. The question is since
you seem to have blown the dust off of Born and Wolf,
do you get the point? Born and Wolf agrees in every
way with Hecht. Total constructive interference yields
an intensity four times the intensity of one individual
wave.

Exactly in accordance with Born and Wolf's equation
(17) in their chapter on "Interference and
Interferometers". Quoting:

"In the special case where I1 = I2, (15) reduces to
I = 4*I1" [for in phase waves].

I'm sorry if you disagree with the laws of physics.
You are not alone in being ignorant of what occurs
when two coherent waves are superposed in phase.
The kicker is that we cannot have two coherent
waves superposed in phase at one location without
having two coherent waves superposed out of phase
somewhere else (assuming no local source).

And so that's your explanation for how 2 Joules per second can be
obtained from a source which is in fact producing only 1 Joule per
second.

Hi Kurt

The local repeater is a good source of a test signal, as you indicate.
In addition, have you considered looking for an amateur satellite on 435MHz?
AMSAT has alot of satellite pass prediction information.

Jerry

As shown by the real-world result for the combined r-f system configuration I posted earlier (and which result I, and many others have measured in real hardware systems) -- one output port of the 3 dB hybrid combiner when powers there are equal and in phase (ie, fully coherent) contains twice the average output power of either tx alone, while the other output port has zero power. These are exactly the conditions in your quote above.

The conflict here occurs because of your belief that the combined, average power in this scenario is not 2X, but 4X that of the individual transmitters.

Or have you changed your mind from what you first posted?

RF

Hi Roy,

Probably in a library. Field work seems to resolve issues too. It
may even prove your speculation in contradiction to mine. Outside of
these authors, we both seem to be shy of "authoritative references" to
parse that Byzantine statement of theirs.

I can only further speculate that BL&H were remiss in specifically
quantifying loss (you aren't asking me for numbers you are already
aware of, are you?), while offering numerous formulaic relationships
of loss against many factors. If we look at their data and observe
that adding radials lowers loss, but not by any precise relationship,
are we left without quantifiable proof, or the obvious implication of
strong correlation? Was there deceit in their arriving at some
conclusions through inference? As Reggie would note, they didn't
actually measure earth at all! Such a retort was met with indignity
in the past, is it now their impeachment?

However, as to counter/anti/clockwise, What impels current to follow
any such presumption? There are two sides to every wire laying in a
plane and phase mappings for earth currents that are symmetrical about
them. To anticipate your challenging me on that statement (clearly
BL&H never, explicitly say this), I can only offer a modest sense of
observing the bleeding obvious. Myself, I don't find BL&H so obscure
to impose this remarkable characteristic that current leaves the wire
on only one side.

Brown, Lewis and Epstein were REPORTING, not inventing, nor offering
pedant readings of scripture. Scribes, such as we are, are free to
interpret within the bounds of their own data, assumptions, and
conclusions. I've offered mine that conforms to many of their points.
If you have your own, you must survive by the same strictures. Given
the specific contention, I am especially intrigued in how you would
answer why the current departed the wire, and where it goes in light
of a potential map created by the phase shifts.

Of course, I regularly obtain 200 watts of forward
power from my 100 watt IC-706. It's all due to
constructive interference.

If you have a bright ring exhibiting 2 joules/sec/unit-area
and a dark ring exhibiting zero joules/sec/unit-area,
don't you see how that averages out to the average
source power of one joule/sec?

NVIS propagation is pretty high angle stuff. If you look at the three dimensional patterns for NVIS antennas you will see that they have a large lobe at high angles and an almost circular omnidirectional pattern at those angles. We're looking at 80 degrees and up mostly here, maybe 70 at the low end....so that antennas are mainly designed to illuminate the patch of ionosphere directly above the antenna.

Ok, I understand that. Your answers to the two questions I asked are that you don't know and you don't know. In the absence of any evidence, I'll continue to disbelieve there's a circumferential component of the current.

No, no, no! The combined average power is 2X. The point
of total constructive interference is 4X. The point of
total destructive interference is 0X. The average of
the total constructive interference and the total
destructive interference is 2X. Seems to me that you
have not been reading and understanding my postings.

You have asked for proof with respect to tipping and you now have
it.So look at the NEC group and you can now argue with them. Oh, and
mention what you did after high school, you may impress them so much
that they will all back down in awe of your antenna knoweledge and the
laws of the masters.
The rest of the group who have argued with you are banking on you to
get the job done with those experts on the NEC group. It's downright
embarrasing
for our group to be on the wrong end of the stick once again. If you
can't
then we can always fall back on "we knew it all the time" so it is not
really the end of the road with respect to tipping of antennas.
If you move to that group you will be among your peers so tell them
what antennas are all about.
Art

Thanks for the reference, but it makes no mention of circumferential currents. At first glance, figure 1 seems to show a circumferential Ih, but the text (as you quoted) clearly calls this a radial current -- the circle in figure 1 turns out to be Hphi, circling the vertically directed current.

Why are you making a trap in the first place? Moxon has a dipole
arrangement with a resonator at the center which is multiband and does
better than a std dipole, might be what you are looking for.

If in fact the power delivered by the "100 watt IC706" radio was indeed 100W, and some directional wattmeter correctly indicated 200W forward, it must indicate 200W-100W reflected which is indicative of a VSWR of 5.8, which should have reduced power output from the IC706 markedly.

Taking another view, if the IC706 will tolerate VSWR of 2 before reducing power (ie and still deliver exactly 100W), then the forward power would be just 113W.

More likely, the IC706 levels its power output on the forward detector, and runs 100W "forward" until the reflected power reaches about 12W whereupon it reduces drive so maintain maximum reflected power <=12W.

Did you make this example up on the fly, or is it the result of actual observation on one or many occasions?

Owen

> constructive interference.

Nice try, but you're kidding yourself if you think you're getting 200 watts out of an IC706.

Back to the laser example, the answer you can't seem to get right is that, recombing the split beam back into one beam will at best recover 1 watt of laser power. That's the limit allowed by conservation of energy as it happens.

> quantitative or explicit statement of your interpretation?

I think, based on the excerpt Richard has provided, it does both. Imagine a leaky hose with water diffusing into the surroundings. So, if you were to integrate over the entire width,or over any region which is symmetric over the wire, the *net* is entirely radial, but if you look at a small region, directly adjacent to the wire, there will be current diverging from the wire as you move outward (assuming current flow is outward... obviously, on the opposite half cycle, it converges toward the wire, as it moves generally inward)...

I suspect one could also analyze it as a wave propagating away from teh wire in the lossy surrounding medium, where the medium has a lower propagation velocity than in the wire. (e.g. imagine a waveguide made with the walls being soil)

Another sort of "hydraulic" model would be if you represented the radials as below grade drainage ditches which have a lot more pitch than the surrounding soil, so the water tends to flow diagonally down the ditch walls.

The interesting question would be whether this is important at all..

One might go through lots and lots of analysis, worrying about the small incremental effects of non-radial current, and find that the inherent variations in soil properties are orders of magnitude larger.

Sounds like a good exercise for a graduate level E&M or calculus class.. you could cast it as a similar exercise in heat flow.. both temperature and electrostatic fields satisfy Laplace's equation.

Nah, no problem.

Connect your rig through a half wavelength of 250 ohm ladder line to a 50 ohm load. Presto, 200 watts "forward power" and 5:1 SWR on the line, and the poor ignorant Icom doesn't have any hint that all those waves of power or energy or whatever are bouncing around on the line, trying desperately but unsuccessfully to overheat the final or whatever they're supposed to do.

Of course, it would take a 250 ohm directional wattmeter to read that "forward power" or SWR. But we don' need no steenkin' meter -- we know it's there, don't we?

Let's see... 600 ohm line feeding a nominally 60 ohm dipole. (It's
not very high above the ground.) 600 ohm line is 1/2 wave long, and
essentially lossless. I feed 60 watts in, the 60 ohm dipole absorbs
60 watts. I suppose the forward power on the line is a bit more than
60 watts. My transmitter doesn't seem to have too much trouble with
the 60 ohm load, though a balun between the unbalanced transmitter
output and the balanced line is nice.

Cheers,
Tom

I made it up but let's take the actual example of
my 33' rotatable dipole on 20m.

IC-706---1WL 300 ohm twinlead---51.5 ohm antenna

The IC-706 is delivering 100 watts. The forward power
is 200 watts. The reflected power is 100 watts. Why
in the world would a VSWR of 5.8:1 on the 300 ohm
twinlead "reduce the output from the IC706 markedly"
when the IC-706 is perfectly matched to a 51.5 ohm
virtual impedance?

As anyone can readily see, I did NOT say I was "getting
200 watts out of my IC706" so your attempt at obfuscation
is obvious. I said "I regularly obtain 200 watts of forward power
from my 100 watt IC-706". Here is my exact configuration
for my 33' rotatable dipole based on actual measurements
on 20m.

100W IC-706--choke--1 WL 300 ohm twinlead---51.5 ohm antenna
Pfor=200W-->
<--Pref=100W

The forward power is indeed 200 watts. I have measured it
with my 300 ohm SWR meter.

Heck, on 17m, I regularly obtain 350 watts of forward power
using a 100W IC-706 as the source.

That's true for average power, Jim, and I have never said otherwise.
But if we observe interference rings, the bright rings can contain
all the power while the dark rings contain none. Thus, the bright
rings represent *double the average power* just as Born and Wolf report.

Shirley, that is not beyond your comprehension. If there is zero
intensity in the dark rings, there must be double the average
intensity in the bright rings to keep from violating the
conservation of energy principle.

The SWR is 10:1 making rho = 9/11 = 0.818 and rho^2 = 0.67
So the SWR is close to 10:1 and the forward power with a
100 watt IC-706 source is about 303 watts. Such is the
nature of constructive interference.

Thanks, but I'm not interested in Cecil's response, since I know for certain that he'll never directly answer the question. Evasion, subject changing, diversion, misquoting, and anything else but solid reasoning or direct confrontation of a problem is all you'll ever get, as each new batch of people joining this group sadly discover sooner or later. I won't see his imaginative but evasive responses anyway unless quoted by someone, since he's one of the four people in my kill file. ("Jesus" is another of the four. I haven't seen any postings by him for quite some time, but there's no harm in leaving him listed in case he's resurrected someday.)

But I'd really like to hear from anyone else who's subscribed to Cecil's unique views of superposition, wave interaction, and bouncing waves of average power (although admittedly these views seem to rapidly morph as necessary to avoid any direct confrontation with rational thought). Or even anyone who believes (as I think you've said you do, Walt) that traveling waves can and do affect each other under any circumstances in a linear medium. Show me how waves can modify each other simply by passing, and any circumstance under which they do. And I'll show you how exactly the same result can be explained without this supposed interaction.

STRAW MAN ALERT! Nobody has said that passing waves
can modify each other. The requirements for wave
modification are very well defined. The two waves
must be coherent and traveling in the same direction
in the same path. Under those circumstances wave
modification is impossible to avoid. When the reflected
waves are canceled in the direction of the source by
an antenna tuner or other matching means, those waves
permanently disappear in the direction of the source.
Seems permanent disappearance meets the definition
of being modified.

So, for example, if I send 50 watts of a sinusoid down a 50 ohm line,
and there's a transition to a 291.4 ohm line that's half a wave long
at the sinusoid's frequency, terminated in 50 ohms, there's no
reflected power on the 50 ohm line. Cool. I knew that. In re-
reading what Roy wrote, I see NO disagreement with that. But in the
291.4 ohm line, there's 100 watts forward and 50 watts reverse. At

the interface between the two lines, there's a total of 100 watts coming in: 50 from the 50 ohm line and 50 from the 291 ohm line. And wonder of wonder, there's 100 watts going out; it happens to all be in the 291 ohm line.

If you go back to Roy's posting in this thread and look at the WHOLE paragraph where he issued the challenge (if you want to call it a challenge), you'll see that you have to come up with an example where there's a node with different power coming out than going in, to be disagreein' with him.

Roy, I was assuming that the instrument was a nominal 50 ohm instrument measuring conditions adjacent to the transmitter.

Your workup is correct enough for the case you describe (though for Pf/Pref=2, VSWR=5.8).

Of course, if you had a coaxial reflectometer calibrated (nulled) for 8.6 ohms or 290 ohms then you would get the same indications on a 50 ohm load, you don't actually need the 8.6 ohm or 290 ohm transmission line.

These are just examples that question the reality of these "component powers" when you can change their magnitude by choosing the reference impedance for measurement or calculation. They reinforce the view that whilst Pf-Pr has meaning (irrespective of Z), Pf and Pr each alone have no meaning.

Owen

Tom, as I noted in another response, I assumed that the observation was based on measurement with a nominal 50 ohm instrument adjacent to the transmitter.

You can of course re-evaluate the forward and reflected power components in a 50 ohm load by changing the reference impedance, and so make them anything you want. Cecil didn't suggest a specific reference impedance, so knowing that the IC706 is designed for a nominal 50 ohm load, it seemed reasonable to make the assumptions that I did.

Make that no *NET* reflected power. Two reflected waves had
to engage in wave cancellation for there to be no net
reflected power. RF waves respond to real-world physical
impedance discontinuities.

> In re-
> reading what Roy wrote, I see NO disagreement with that. But in the
> 291.4 ohm line, there's 100 watts forward and 50 watts reverse. At
> the interface between the two lines, there's a total of 100 watts

> wonder of wonder, there's 100 watts going out; it happens to all be in
> the 291 ohm line.

Let's analyze that example:

50W--50 ohm line--+--1/2WL 291.4 ohm line---50 ohm load
Pfor1=50w--> Pfor2=100w-->
<--Pref1=0 <--Pref2=50w

The physical power reflection coefficient is 0.5. So Pfor1
splits into two parts, P1=25w being transmitted and P3=25w
being reflected. Pref2 likewise sees a power reflection
coefficient of 0.5 and splits into two parts, P2=25w re-
reflected and P4=25w not re-reflected.

Since Pref1=0, total destructive interference exists toward
the source.

Pref1 = P3 + P4 - 2*SQRT(P3*P4)

Pref1 = 25w + 25w - 2*SQRT(25w*25w) = 0

The associated S-Parameter equation is:

b1 = s11(a2) + s12(a2) = 0

P3 and P4 are the reflected wave components associated with
wave cancellation.

On the constructive interference side toward the load:

Pfor2 = P1 + P2 + 2*SQRT(P1*P2)

Pfor2 = 25w + 25w + 2*SQRT(25w*25w) = 100w

The associated S-Parameter equation is:

b2 = s21(a1) + s22(a2) where |b2|^2 = 100w

Everything is perfectly consistent. Where is an error?

> If you go back to Roy's posting in this thread and look at the WHOLE
> paragraph where he issued the challenge (if you want to call it a

Well, if Roy is asking for proof of violation of the
conservation of energy principle, his concept of
"sloshing" energy comes pretty close.

Very good info. The interesting thing is since my original post I
went and bought a 500 ft roll of Carol Brand RG-6 QS from Home Depot,
and made some cables with the crimp-on connectors I already had. When
I swapped these new RG-6 QS cables with ones I made a while back with
regular RG-6 with the same crimp-on connectors, I got surprisingly
horrible results. A couple of analog channels don't come in at all
(ch 28 and 56), where they used to come in with a fairly good picture.
Yet other channels on lower frequencies, such as VHF appear to be the
same. I inspected the connectors and they appear to be OK, but I am
guessing there must be an issue with these connectors and the RG-6 QS,
where it's causing the issues that were described above with loss. Is
this possible?? It seems to be affecting various UHF channels (ch.
28, 56, 62).

Thank you very much for the help.

Some thoughts:

If you have 12W of audio and you want to use plate and screen modulation, you have enough to cover 24W of DC input at 100% modulation, but it wouldn't hurt to have a slightly higher powered final with 60% to 80% modulation. That would suggest up to about 36W input, which at 66% efficiency would give you a 24W carrier, 66% modulated. In that case, you would need a PA tube with more than 12W of anode dissipation. The 2E26 has an ICAS plate dissipation of 12W.

One approach is to choose a tube that is likely to remain available due to its widespread use and the consequent replacement demand. I don't think the ones you nominate would be high on that list. Although a 6146B might seem overkill, it is cheap, can run comfortably from a 500V supply at good efficiency, and will idle along at about 60% of CCS ratings.

Important factors will be the supply voltage and anode current compatibility with your modulation transformer... otherwise your 12W of audio might not go very far at all. The 2e26 has less room to move in accomodating your mod tranny than the 6146B.

Then your observation was unrelated to the topic of discussion, which
was your claim that 2 Joules per second could be obtained from a 1
watt laser. It must have been offered as a diversion.

> Heck, on 17m, I regularly obtain 350 watts of forward power
> using a 100W IC-706 as the source.

It's certainly an impressive meter reading. It is your contention
then that interference caused a 250 Joule per second increase in the
amount of energy being produced by your radio? If not, then this must
also have been offered as a diversion.

>> Back to the laser example, the answer you can't seem to get right is

>> 1 watt of laser power. That's the limit allowed by conservation of
>> energy as it happens.
>
>
> That's true for average power, Jim, and I have never said otherwise.

You can't average power 'going' one direction with power 'going' in
some other direction. That doesn't even make sense. If you
integrate all of the energy, from all the bright fringes it still

doesn't exceed the energy coming from the source.
There is no amount of hand waving that can cause a one watt laser to
deliver 2 Joules of energy per second.

> But if we observe interference rings, the bright rings can contain
> all the power while the dark rings contain none. Thus, the bright
> rings represent *double the average power* just as Born and Wolf report.

Born and Wolf doesn't discuss power and interference, and they
certainly don't interchange intensity and power in their discussions
like you do. There can be no more 'power gain' along a transmission
line than there can be along a beam of light. With respect to
antennas one can obviously observe an increase in power in a
particular direction given the fact that antennas do in fact
redistribute energy by generating an interference pattern. But even
with all the interference and power averaging taken into
consideration, the radiated power will still not exceed the input power.

You can't get 400 watts to a load using two 100 watt PA's no matter
how much interfering and averaging you do, Cecil. How can you even
make that claim with a straight face?

> Shirley, that is not beyond your comprehension.

Quite honestly it does seem to be beyond yours. And please stop
calling me Shirley. :-)

Sorry for the previous blank reply posting.

A polarization story, if I may. At Field Day a few years ago, I decided to try a few 446 MHz calls to add to the fifty-some 2m QSOs I had logged. I got bupkus for an hour's work. I tried a local repeater and got a similar nothing, so I concluded my radio had quit. No, I had the yagi antenna horizontal. I had been playing at home with UHF TV and I simply translated the orientation of the TV yagis to my 70cm yagi. Dumb! Everything was fine except for my being cross-polarized with the rest of the 70cm FM universe.

I understand that SSB'ers are horizontal on VHF/UHF; if I ever get an allmode, I'll have to remember that.

Jim Kelley wrote:
> Then your observation was unrelated to the topic of discussion, which
> was your claim that 2 Joules per second could be obtained from a 1 watt
> laser.

You know that I never claimed that, Jim. As bright a guy
as you are, why do you have to stoop to falsifying what
I have said?

If the average intensity is one watt per square inch
and we cause interference, the intensity of one particular
square inch can go to zero in the case of total destructive
interference. Since that energy has to go somewhere, it
goes into constructive interference in some other square
inch. If it is total constructive interference, we will
indeed double the average intensity to two watts per square
inch. The total power is still the same but the power
density has doubled in half the area while going to zero
in the other half of the area.

Hint: (2 watts/in^2 + 0 watts/in^2)/2 in^2 = 1 watt

> It's certainly an impressive meter reading. It is your contention then
> that interference caused a 250 Joule per second increase in the amount
> of energy being produced by your radio?

Of course not. That's another false implication of yours.
The interference causes the forward power to be 250 watts
higher than the output of the source. Such is the nature
of constructive interference. The reflected power is 250
watts. |Forward power| = |source power| + |reflected power|

> You can't average power 'going' one direction with power 'going' in some
> other direction.

I didn't know we had two directions in the laser example.
I thought both beams were going the same direction. If the
beams are going in opposite directions, we get standing
waves and that changes things. If your split beams were
going in opposite directions, I misunderstood the example
and you can forget everything I have said about it.

> If you integrate all
> of the energy, from all the bright fringes it still doesn't exceed the
> energy coming from the source.

That's what I have said all along, Jim. You are obviously
trying to set up some sort of straw man. The energy in the
bright fringes exceeds the average energy. That is all
I have ever said.

> There is no amount of hand waving that can cause a one watt laser to
> deliver 2 Joules of energy per second.

Of course not and I never said it would. Please stop trying
to imply that I said something that I never said. It is
downright unethical to debate in such an unfair manner.

> Born and Wolf doesn't discuss power and interference, and they certainly
> don't interchange intensity and power in their discussions like you do.

Intensity is power density. I have a habit of saying power
when I should have said power density. For that I apologize
and will try to break myself of that habit. But you can
always tell by the context that I was talking about power
density.

> There can be no more 'power gain' along a transmission line than there
> can be along a beam of light.

On the contrary, reflection gain from a tuner is an
accepted concept within the wave reflection model.

> But even with all the interference and power
> averaging taken into consideration, the radiated power will still not
> exceed the input power.

Nobody believes the conservation of energy principle can be
violated so that is just another one of your straw men. Go
ahead, be my guest, and knock it down if it makes you feel
better. Nobody cares.

> You can't get 400 watts to a load using two 100 watt PA's no matter how
> much interfering and averaging you do, Cecil. How can you even make
> that claim with a straight face?

I didn't make that claim. I said that Keith would have to prove
it was possible before his assertions made any sense. I challenged
Keith to prove that was possible. I certainly have never made that
claim. You usual lack of ethics is showing. If you are forced to
lie to make your point, your point is not worth making.

Bart,

Thanks for the thought. Modeling predicts it is much lower then that;
however I don't want to overlook anything. The Q looks very good on the
network analyzer, however I have never run the math. The coil is about
3.3 inches in diameter. I will let you know.

Jim Kelley wrote:
> You can't get 400 watts to a load using two 100 watt PA's no matter how
> much interfering and averaging you do, Cecil. How can you even make
> that claim with a straight face?

I didn't make that claim. I challenged Keith to prove it
was possible. Only then could he claim that sources
obey the rules of superposition.

But let's talk about superposing two 100 watt waves
in a 50 ohm transmission line. Never mind exactly
how it is accomplished for now.

Wave1 = 70.7V at 0 deg and is 70.7^2/50 = 100 joules/sec
Wave2 = 70.7V at 0 deg and is 70.7^2/50 = 100 joules/sec

Please superpose those two coherent waves within a 50
ohm transmission line and see what answer is obtained
for total voltage and total power.

Hint: Power = V^2/Z0

You can visualize the superposition by going to the
following web page and setting both phases to zero.

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index

Right. That's my point. So, what I'm claiming ... and trying to get
someone who knows more about this stuff than I do (which is just about all
of you) to confirm or deny ... is that with an NVIS dipole, someone 100
miles away from me would not be able to perceive the difference if my
antenna was broadside to him or oriented in line with him. True, or false?

Owen,

The antenna is a short loaded vertical. The base is about 1.1 meters
long and 90mm in diameter, the coil is about 160mm long and about 80mm
in diameter, the top is 3 meters. The coil wire is 12 gage and the
spacing is about .5. As a model cross check, the impedance of the coil
measures about 60 uH.

The broadside radiation is mostly horizontally polarized
while the radiation off the ends is mostly vertically
polarized. I wonder if that would make a measurable
difference?

Hi Owen,

(Noted your other response, to my posting, about the assumption of 50 ohm line. I obviously didn't make that assumption...)

I've been harping in this forum for YEARS about the need to calibrate an SWR meter or a return loss bridge to the impedance you're wanting to use it for. I'm always somewhat amazed that some folk just "don't get it." Thanks for helping reinforce the need for the proper calibration. Those bridges are not magic; they can only measure voltages or currents produced by (hopefully) linear combinations of transduced line voltages and currents. I think it was about ten years ago in this group that I posted the derivation of the equations to determine forward and reflected from measurement of voltage and current at a point on a TEM line, IF you know the impedance of the line.

Cheers,
Tom

So, what do you think its impedance would be? 1500+j??

This is probably accounting for somewhere between 5 and 15 ohms of
additional resistance, depending on Q.

Most likely TRUE. Other conditions may affect the signal but for the
most part the signal goes almost straight up in all directions and
almost straight down in all directions. Your coverage can be up to 300
to 500 miles depending on conditions. The MUF for NVIS is dependent on
the position of the sun and drops drastically at and after sun set.

Duh, ??+j1500 is more like it.

Same outcome, it is probably accounting for 5 to 15 ohms of resistance that
you haven't included in your calcs.

Hi Tom,

I guess it is the misconceptions about these things that drive us to write such stuff.

I drafted an article recently showing what the typical SWR meter samples, and the use of that information, including treatment of Pf and Pr as stand alone values. The article is at http://www.vk1od.net/VSWR/VSWRMeter.htm .

I thought that was the meaning of this para that I wrote for you before:

NVIS isn't strictly about the zenith, but an antenna that is omni at the zenith, and doesn't have deep nulls (dipole low over real ground), is close to omni at high elevations. The exact variation will depend on frequency, mounting height, ground parameters, and leg angles if an inverted V. If you could rotate such a dipole, I would defy you to reliably measure the out-of-omni above 50 deg elevation with an S meter.

Hi Owen,

I had a quick look at your article. Though I didn't try to proof-read
it for accuracy, I was reminded that the equations I posted those long
years ago said that if you know the _instantaneous_ voltage and
current at a point on a line, and know its impedance (as a frequency-
independent quantity), the equations apply, and you can resolve that
instantaneous pair of values into forward and reverse. That's
something that's not immediately obvious when people think only about
sine waves.

Cheers,
Tom

I've worked in the cable TV industry for nearly 44 years, and have NEVER found that a certain type of male F-connector is, in itself, responsible for 'horrible results' in terms of RF throughput. Provided that (a) the shell makes good contact with a few strands of the braid, (b) you haven't managed to wind a strand of the braid around the inner conductor, and (c) you haven't left a thin film of the dielectric on the surface of the inner conductor (yes, I've done all of these!), the connector WILL appear to work normally. All that suffers is the screening effectiveness and mechanical reliability.

Regarding whether some male connectors create a significant mismatch due to crushing of the dielectric, even if this does happen, is not going to be significant in normal use (up to at least 2GHz) until the outer conductor is almost touching the inner. You can easily prove this for yourself by looking at the RF throughput of a piece of coax, while progressively crushing it with a large pair of pliers.

The thing which causes the most noticeable impedance mismatch is normally the female part of the connection. Connectors with a 'duck-bill' inner (two parallel fingers) tend to be more capacitive than those with a 'tulip' (three or four fingers). They are also likely to make a less reliable ohmic contact.

Don't get me wrong. I do not advocate sloppy practices when fitting connectors. In the UK, the compression and 'snap-and-seal' types are the de facto standard. However, I would not hesitate to use crimp or screw-on types for home use, provided you know how to fit them properly. And I do.

If it is this part, this is just another one of Roy's
straw men. Nobody in the world is saying that the wave
reflection model violates the conservation of energy
principle. In fact, the wave reflection model does more
to preserve the conservation of energy principle than
Roy's notion of "sloshing" energy going nowhere.

It would be highly valuable if you would point to any step in
my solutions that require that 100 + 100 equal 400. I certainly
have never stated this.

I know I have previously offered solutions that you have declared
incorrect but you have been unwilling to point to the error.

I have also offered to check your solution but you have never
offered one, apparently because your analysis techniques are
inadequate to solve the problem.

...Keith

PS Should you wish to try, recall that the problem was a signal
generator with a 450 Ohm output impedance driving a 450 Ohm line
connected to a 75 Ohm load. What is the magnitude of the re-reflected
signal at the generator? That is, what is the magnitude of the ghost
created by the reflected signal? (And you can't make changes to the
problem to solve it.)

> for total voltage and total power.
>
> Hint: Power = V^2/Z0

Oh yes, let us do this.

70.7 + 70.7 -> 141.4
141.4**2/50 -> 400

100 + 100 -> 200

But 200 is not equal to 400.

So which was the invalid step?

Adding the voltages together? (Might mean superposition is invalid?)
Or adding the powers together? (Might mean no conservation of
energy?)
Or perhaps V**2/Z0 is invalid? (Maybe this is the best choice?)
Or 200 is equal to 400? (This would be messy!)

For full marks, explain your answer.

> Pfor1=50w--> Pfor2=100w-->
> <--Pref1=0 <--Pref2=50w

You are very comfortable with this style of example, you analyze it
well,
and the numbers confirm your expectation.

But a good theory works for more than just one example.

Why don't you analyze my example:

Generator with
291.4 Ohm ------------ 291.4 Ohm line ---- 50 Ohm load
Source Impedance Pfor2=100w-->
<--Pref2=50w

What is the power emitted by the generator into the line?
Where does Pref2=50W go?
Are there ghosts?
What is the magnitude?
What power would the generator emit if the line was terminated
with 291.4 Ohms?

Please do not modify the example for analysis since this may change the results.

There is much to be learned by trying examples that may challenge your expectations.

4091. Why S - Parameter at High frequencies?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-10 11:21:46 UTC
From: ilam <ilam.paridhi@gmail.com>
Message-ID: <1176204106.659945.83650@n76g2000hsh.googlegroups.com>
Source record: 43207

I am in a process of understanding the importance of S-Parameter at high frequencies, please answer my following questions:

1. Why Measuring a wave (voltage or current) is more easier than volage and current? (Why measuring S-Parameter is more easier than other parameters?)

2. How the voltage and current waves are measured?

Measuring voltage and current are difficult at high frequncies, that is why S-Parameter is more useful at high frequncies. Is the same thing is true for simulation?

Regards,
Ilam

This thread has been a hoot - I just about snorted my coffee out my
nose a couple of times, reading this in the early AM...

Just to muddy the waters nicely, here is an excellent demonstration of
something for nothing, i.e. faster than light propagation by
constructive wave interference called "supraluminal propagation"..

http://gregegan.customer.netspace.net.au/APPLETS/20/20.html

Lets see, for starters assume that the constructively interfered wave
is propagationg at 1.2C it means that E = (MC^2)^1.2 right????

Andy comments:
I remember seeing something similar where a coax feedline had
the center conductor connected to 1/4 wavelength of wire, and
then 1/4 wavelength down the coax feedline, the coax was wrapped
thru a
toriod, which decoupled the "outer surface" but didn't affect the
inner power flow which was common mode..... Seems to me that it would
work the same
way.....
Anybody seen this, or have a name for it ?

Being that I have zero qualifications as an expert on C I will tell
you how I see it.. <pun intended>

First, C is specified as the speed of photon travel in a vacuum, per
definition... Or as our attorney brethern say it, Per Se...

Second, C' is the measured speed of the propagation of the wave front
we call light through an atomic medium, air, water, glass, diamond,
etc....

The thing to keep in mind is that the two, C and C', are not identical
physical entities...
C is the unimpeded propagation of a photon - i.e. a single entity -
through a non atomic medium we call a vacuum - 'aether' if you will...
The photon that left Proxima Centauri ~4 years ago is the same photon
that slams into the front lens of the Hubble telescope (according to
that photon's wrist watch that ~4 years happened instantaneously, but
that's another rant)...
Now if you were in orbit at the eyepiece of the Hubble the photon that
enters your retina is not the same Proxima Centauri photon that
slammed into the Hubble's mirror... And that makes all the
difference...

C' happens when the photon smashes into the Hubble's glass and is
caught up in the electrical fields sorrounding the atoms making up the
glass, primarily the electrical field of the outer (valence) electrons
of the Protons... Like a house fly at full speed hitting a spiders web
the photon begins to tumble and veer sideways and rapidly decellerate
causing it to dump it's energy, i.e. radiate an electromagnetic field
of it's own... The electron's field absorbs the energy radiated off
the photon, causing in increase in the electrons energy level, usually
forcing it to jump to a higher 'orbit'...

Now at this instant the photon has disappeared (eaten by the spider)
and the electron has been pumped up (like Hulk Hogan)... After a short
interval the electron drops back to a lower energy level emitting a
new photon... This photon takes off like a scalded rabbit at C (or
very near C) but doesn't get far before another electron field sucks
it up again... And so it goes for the passage of the photon (actually
information) through the atomic structure of the transparent
material... The photon that pops out of the eyepiece and slams into
your retina is the lebenty sebenth generation descendent of the
original photon that hit your scope... The process of repeated
absorption and emission of a photon by multiple electrons is what
slows the light (wave front) when it travels through transparent
material... (and also what creates refraction, circles of confusion,

and a bunch of other phenomena)

Clear as mud, eh wot...

Chesapeake Springfest this coming Sunday morning, April 15th, same place as last year. Location is the Moose Lodge #898 on Geo. Washington Hwy. (Rt-17) just south of the Portsmouth/Chesapeake city line. Early setup 6:30 AM $5/6 inside table while last, 7500 sqft. Tailgate over an acre. General public $6 open at 9:30 AM. Door prizes - Kodak Digital Camera, VX-150 2M HT, LDG Z100 auto tuner and more every 15 minutes.

> have never stated this.

I went over this before. In order for a source to
obey the rules for superposition, it must be linear
enough to engage in constructive interference. That
means it must be able to double its voltage and double
its current at the same time in order to supply the
total constructive interference energy requirements
required by superposition of coherent waves. No
commercially available amateur radio transmitter that
I know of will do that. Therefore, your simple proposed
method will not work on the average amateur radio
transmitter because it is NOT LINEAR. All you can do
is invent sources in your head. I'll bet you can even
leap tall buildings in a single bound, in your head.

> I have also offered to check your solution but you have never
> offered one, apparently because your analysis techniques are
> inadequate to solve the problem.

Yes, they are as are everyone else's, including yours.
That's why there has *never been a solution* and the
argument continues to rage after decades. If anyone
had ever figured it out, we wouldn't be having this
discussion.

You and I are looking at the moon. You assert that it
is 1000 miles away. I say that's wrong. You ask me how
far away is it? I answer that I don't know but I know
it is not 1000 miles away. You say that since I don't
know how far away the moon is then it has to be 1000
miles away. That's where our present argument stands.

The reflection coefficients are measurable physical entities
and there is a well-defined procedure for measuring them.
Virtual reflection coefficients, such as the ones used by
hams, are not used with S-Parameters. That's an advantage.
The voltages are normalized to the characteristic impedance
of the transmission line and everything obeys the rules of
the wave reflection model.

There are certainly other methods of analysis, h-parameters,
Z-parameters, etc.

The problem with some of the other parameters is that
short and open circuits are required to obtain the data.
This can cause instability in active devices.

Frank

> But 200 is not equal to 400.
>
> So which was the invalid step?

There was no invalid step. The two coherent waves engaged in
total constructive interference just as they do in a Z0-matched
transmission line in the direction of the source. The extra
200 watts is supplied by total destructive interference at
the Z0-match in the direction of the source. 200 watts of
reflections have been eliminated toward the source and join
the forward power wave toward the load. In ham terms, all
the reflected power has been re-reflected.

The S-Parameter equation yields the same results where
b2 is the normalized voltage flowing toward the load.

s21(a1) = 70.7V/SQRT(50) = 10 [s21(a1)]^2 = 100W

s22(a2) = 70.7V/SQRT(50) = 10 [s22(a2)]^2 = 100W

b2 = s21(a1) + s22(a2) = 141.4V/SQRT(50) = 20

|b2|^2 = 20^2 = 400W = the forward power

constructive & destructive interference is built right
into the S-Parameter analysis. Forward and reflected
waves are built right into the S-Parameter analysis.

There was no invalid step.

Any example where reflected energy is allowed to
reach the source cannot be analyzed in any valid
real-world way. That is what the decades-old
argument between experts is all about. There has
never been a valid way to analyze such a real-world
system. Of course, you can analyze this system in
your mind but real-world results with real-world
ham transmitters will prove your analysis invalid.

If there existed a valid way to analyze real-world
ham transmitters with incident reflections, everyone
would be using that method but, so far, bench
measurements prove that no valid analysis exists.
And so the argument continues to wage on. You
are not going to resolve it with a simple-minded
model that exists only in your mind and not in
reality.

Replace the above purely imaginary generator with an
IC-706 and get back to us.

And that, in a nutshell, is why Keith's analysis
is invalid for real-world ham transmitters. In
a real-world transmitter, incident reflected
waves do not flow through the source like they
do in the model in the human mind.

Cross-posted to: comp.dcom.cabling,rec.video.cable-tv,alt.home.repair,alt.cable-tv,rec.radio.amateur.antenna

At a trade show several years ago, a vendor demonstrated the effects stapling cables could have on signal transmission. He took a VCR, a ch. 3 modulator and a piece of drop cable and attached the cable to a piece of wood utilizing a regular staple gun that you buy at any home improvement store. Used the gun as most people would, and inspection of the cable showed it to be fine (undamaged). By the seventeenth staple, ch. 3 was completely gone..

It doesn't take major crushing to create mismatch, and as to whether it is significant sort of depends on what happens to be trying to get through at the particular point where the mismatch occurs.

At http://www.cencom94.com/gpage.html9.html, there is a picture of a sweep trace of some cable with hex-crimp connectors (gotta scroll down a little).

Hewlett-Packard were one of the early proponents of using S-parameters for calculations as well as for measurements. HP had a vested interest, in that they were one of the first companies to make accurate instruments for measuring high frequencies, up into the microwaves. Part of that effort was customer education, and there are some good applications notes from HP about S-parameters, and about RF measurements in general. You should be able to find many of them on the internet, with a bit of searching. Some of them deal with accuracy, and in them you should find answers to your questions. You'll find a great deal more than just those answers.

Measuring voltage or current at audio frequencies is easy enough. But how do you measure a current at 10GHz without disturbing and changing it? How do you accurately measure a voltage at that frequency, when the tiniest of capacitances will change the reading? But if instead you want to measure the standing wave ratio on an accurately-made piece of transmission line, that can be done relatively easily, and especially you can determine when the standing wave ratio goes to zero: when there is no variation in voltage along the length of the line. Then too, you can build a bridge circuit to enable measurements at a particular impedance. 50 ohms is convenient, though it's somewhat arbitrary. If you pick too high or too low an impedance, you run into the same difficulties as if you try to measure a voltage or a current, but at impedances between perhaps 20 ohms and 100 ohms, in a coaxial-line environment, you can build loads--resistors--that accurately terminate the line, and you can build a Wheatstone bridge circuit, essentially, that will tell you if you have a load that's the impedance of the bridge arms. The bridge is the most sensitive at

balance, when all the arms are the same impedance.

Also note that while it's very difficult to measure current or voltage accurately at high frequencies, if you can build a resistive load, then measuring power accurately is possible. When you are first starting, you can measure power by determining the temperature rise of a load resistor, which you made by trimming things carefully so that there were no standing waves on the precision line feeding that resistor. You can calibrate that quite accurately by feeding it DC power, to determine the temperature rise per watt. If you learn to make very tiny resistors and measure very smal temperature differences, you can make a thermal bridge that can detect power at a low level accurately.

Let us know if you have trouble finding the HP applications notes...look for S-parameter notes, and look for notes on making accurate measurements with (vector) network analyzers. Also, do a search for information on the history of RF and microwave measurements.

For simulation, it is simply convenient to work in the same domain as you make measurements. As you note, there are other parameter sets that give you equivalent information, and with modern computers, there is effectively no loss of accuracy if you deal in any other set of parameters used for 2-port (or N-port) networks. But do note, please, that these are linear parameters, and they won't give you information about nonlinearities, either ones you wanted as in frequency mixers or ones you didn't want, that cause unwanted distortion.

Cheers,
Tom

Source record: 43214

Dear Rick (no call sign):

A 0.5 WL dipole almost on the ground will be inefficient. What the dipole does radiate will, at high take-off-angles, be close to circular (independent of azimuth) well past 100 miles.

If both efficiency and circularity are important, an excellent solution is what the CCIR calls a TR2/2/.2. That is two, parallel one-wavelength dipoles both in a horizontal plane 0.2 WL above the ground that are 0.5 WL apart. With the dipoles fed in the middle with equal lengths of open line that meet at a point midway between the dipoles, one can achieve a reasonable input impedance.

In any case, I suggest you avail yourself of the benefit of raising whatever you use to a height of something like 0.2 WL and less than 0.3 WL.

Owen,

Are you referring to the coil alone? You are correct the coil accounts
for a significant part, probably between 4 and 8 Ohms.

I am measuring real values between 52 and 56 Ohms with 0j. This varies
mainly with moisture.

So let's say the total antenna is 12 Ohms. If the measured value is 52
that says the ground is 40. This puts us back to the original question:
why is the ground so high?

- Dan

The circuit

Now just above, you started with 100W + 100W and ended with 400W. And you wonder why readers think you advocate this position.

Does this not cause you some discomfort? It clearly violates conservation of energy.

For me, it is pretty clear. If you start with 200W, you can not end up with 400W.

A strange assertion. Consider two wire phone lines; transmitter
and receiver at each end. Consider cable modems; ditto. Consider
computer busses; ditto.

I am sure you will find a "good" reason why either these are
special cases or amateur RF is a special case and therefore
something does not apply.

Oh well.

Cecil, W5DXP wrote:
"Antenna gain over isotropic is an application of constructive interference."

Yes. An often offered annalog is an inflated spherical balloon. It contains the same amount of air no matter how it is squeezed. Sqeeze it one place and it bulges elsewhere.

An isotropic antenna, could one be constructed, would radiate equally well in all directions. As a radiation pattern becomes lopsided, the bulge is filled with the energy squeezed from elsewhere.

Directive gain of an antenna is a power ratio. It`s the power that you would have to put into an isotropic wersus the power you have to put into the gain antenna to lay the same signal on a point in the preffered direction.

Other things equal, if a gain antenna radiates twice the power in the preferred direction as an isotropic, it has a gain of 3 dBi.

Best regards, Richard Harrison, KB5WZI

I think polarization will play in the picture. Dealing with NVIS, we do not get much of the polarization being rolled around as with signals coming from refractions/reflections via ionosphere.
The signals at the receiving end would be coming from "above", but I would suspect that with distinct polarization component that should be detectable with receiving antenna if rotated.
So I would vote that there would be difference in NVIS signals most likely characterized by sharp minimum at the opposite polarization receiving antenna orientation.
Any RF signals have a distinct polarization at any point and time.
Add some constructive or destructive interference and one would get the picture.

An electrician confusing grounding and bonding - that is pretty funny.

From the US National Electrical Code
ï¿½250.50 Grounding Electrode System
All grounding electrodes as described in 250.52(A)(1) through (A)(6)
that are present at each building or structure served shall be bonded
together to form the grounding electrode system.ï¿½

ï¿½250.52(A)(1) Metal Underground Water Pipeï¿½
(10 feet or more metal in earth)

Using underground metal water pipe as a grounding electrode is REQUIRED.
And this has been a requirement for a very long time. Local codes may be

different from the NEC, but it is unlikely they are different on this.

And if you just "bond" metal water pipe it will work as a grounding
electrode anyway.

No, but very interesting. I was going to try this, to see if it would work.
Should be able to use a 1:1 commercial current balun at the point 1/4 wave
down the coax. I think you do not take the coax propagation velocity int
account. There is also triaxial cable.

I bought one of the CondoBuster antennas off ebay. I figured for $20 or so I couldn't go wrong.

This is one of those love or hate antennas. Strangely enough, most of the hate postings on the antenna are from people who have never used one. Anyhow, in my cast, the antenna was evrything the ad said it was. I live in a second floor condo in a highly restrictive complex, where little old ladies go around looking for condo rule violations because they don't have anything else to do.

We have a large balcony with a peaked roof over it. I just stapled the center of the CondoBuster under the peak at the apex and then ran the antenna down each side of the peak. I fed it with RG-58 for about a 25 foot run to the TS-850.

I am here to tell you that it works great. I have been off the air for about four years. It is really a pleasure to be able to fire up my TS-850 and actually talk to people. I can work just about anything I hear.

The antenna is build for 10 through 20 meters, but I have been able to load it on 40 meters with the internal tuner in the TS-850. It only loads from about 7200 to 7250, but that is better then nothing.

If you are no able to get on the air because of local antenna restrictions, I would highly recommend trying one of these.

A periodically repeating mismatch, such as the one produced by the staple demonstration, can cause extreme effects as the demonstration showed. This is a very much worse case than a single mismatch.

True enough but there is a difference, grounding is connecting to earth bonding is tying conductive structures together so they are at equal potential. Ground is a single point that everything else is bonded. Ground should be a stucture that the qualified electrician should be familar with not plumbing that may or may not be intact. If you dont believe me just try to get an electrical inspection on a new home without a ground rod installed.

BTW the NEC is a minimum standard not a guide on how to wire your house.or perform grounding and bonding.

You wouldnt believe what electricians dont know, like checking phase rotation before turning on a new 200KW UPS. or megging out lines before turning on new parking lot lights or making sure a generator is not backfeeding a line before working on it. All things I have seen electricans screw up in the past year.

> I have said?

So now you start with the accusations, and here's why (from
yesterday):

"If it were total constructive interference, two 1/2W
beams would yield an intensity of 2 watts."

It was pointed out to you that that notion violates conservation of
energy, but rather than admit that you were incorrect, you attempt to
revise history. Then there was this:

> Hint: (2 watts/in^2 + 0 watts/in^2)/2 in^2 = 1 watt

:-) Actually, it's a beam of light that subtends a solid angle of
less than one degree. Let's call it a degree just to be
conservative. That would leave 719 other solid degrees where there is
0 watts, so according to Cecil's theory of spacial power averaging,
the answer could also be 2 watts+0+0+0... / 719 = 2.78 milliwatts.
But apparently those values don't give the answer you were going for.

Others have made points along these lines quite eloquently. Excellent
comments in this thread from Roy, Keith, Owen, Gene, Tom, et al.

Stapling - or any other small mismatch repeated at regular intervals -
can indeed produce a severe structural mismatch (with the associated
suckout) at frequencies where the intervals are one wavelength, and
multiples thereof. However, the presence of a one-off connector where
the match is distinctly questionable will usually go completely
un-noticed (except to the most discerning of engineers). I still
maintain that any problem will be because there is no proper continuity
through the connector, or possibly an inner-to-outer short (maybe
partial). I must admit, I haven't used an RF TDR in earnest for over 20
years. I have found that, if it buzzes out OK at DC, it will generally
be OK at RF.

Hello Rick,

At 100 miles distance, the TOA is almost vertical (maybe 75 degr), so
with respect to signal strength, it is practically impossible to
detect whether the antennas are broad side. Because of the distance,
ground wave propagation loss is far higher with respect to NVIS
propagation loss under these circumstances.

One would mention polarization of the waves going up and down. I
would not matter about this. These low frequencies are strongly
affected by faraday rotation. On the way up and down, the polarization
rotates several times and several wave fronts do exist.

While you transmit (nearly vertical) with linear polarization, the
down coming wave may have a strong circular component.

With respect to the radiation pattern, you are right, the differences
in pattern are minimal below 30 feet. However the overall efficiency
is strongly depended on antenna height and soil properties. I did some
simulation and practice. I made a short document of it (for JOTA
porpuse), however the document is in Dutch Language (http://
www.tetech.nl/divers/NVISantenneNL1.pdf). Maybe you can get some
useful info out of it. At low heights, much power is dissipated into
the ground (resulting in a useful bandwidth).

Best Regards,

Wim

I don't recall that you have told us where the coil is located, and I am not going to build a model to discover something that is relevant and that you could have told us.

You have told us the coil had an "impedance" of 60uh. If it had an inductance of 60uh, it would have an impedance of 1500/Q+j1500 where Q at 3.9MHz for a practical coil is likely to be above 100 and less than 300. The resistive component of the coil has to be referred to the feedpoint so that you can deduct it from the total feedpoint Z. The best way to do that is your NEC model.

You should be able to form a better range for the equivalent coil loss at the feedpoint than you stated above (since you seem to have the means of measuring the coil and inserting the values in your model).

> I am measuring real values between 52 and 56 Ohms with 0j. This varies

>
> So let's say the total antenna is 12 Ohms. If the measured value is 52
> that says the ground is 40. This puts us back to the original
> question: why is the ground so high?

You also previously said "... Even if the antenna were 6 to 8 Ohms the ground loss would be at least 42 to 44 Ohms."

I read this to mean total system R is 50 ohms.

In this post it is reported between 52 and 56.

The other issue that Frank raised is the elevated feedpoint and whether you modelled that correctly. The radiation resistance you quoted seems (without checking) reasonable for a short monopole over ideal ground, but one expects it would be higher for an elevated feed point. Have you modelled the antenna you built, or have you build an antenna you cannot model accurately and are applying model results incorrectly to the thing you have built?

Though you see only one question, "why is ground 40 ohms", you haven't disclosed enough information in your posts to convince me that it is 40

ohms. If you ask the wrong question, you might not get a useful answer.

Is ground 40 ohms?

Owen

> Now just above, you started with 100W + 100W and ended with
> 400W. And you wonder why readers think you advocate this
> position.

100W + 100W is not all we started with. Somewhere
else is 100W + 100W of destructive interference
that adds up to zero.

This is very much like the equation in Born and Wolf.

Itotal = 4I1 where I1 = I2 = 100 watts/unit-area

Such is the nature of constructive interference. That
you are ignorant of such is noted.

> Does this not cause you some discomfort? It clearly
> violates conservation of energy.

Absolutely NOT! There is 200 watts of destructive
interference somewhere else. Here is a real-world
example:

---291.4 ohm line---+---1/2WL 50 ohm line---291.4 ohm load
Pfor1=200W--> Pfor2=400W-->
<--Pref1=0W <--Pref2=200W

On the load side of point '+':
P1 = Pfor1(1-rho^2) = 100W
P2 = Pref2(rho^2) = 100W

P1 + P2 + 2*SQRT(P1*P2) = Pfor2 = 400W
(200W of constructive interference)

On the source side of point '+':
P3 = Pfor1(rho^2) = 100W
P4 = Pref2(1-rho^2) = 100W

P3 + P4 - 2*SQRT(P3*P4) = Pref1 = 0W
(200W of destructive interference)

> > beams would yield an intensity of 2 watts.

That should have been 2 watts per unit-area. Note that
I did NOT say two 1/2W beams would yield a power of 2
watts. The correct dimensions of intensity would be
2 watts/unit-area, a power density, not a power. I have
already apologized for that goof in dimensions.

> It was pointed out to you that that notion violates conservation of
> energy, but rather than admit that you were incorrect, you attempt to
> revise history. Then there was this:

No, that notion *DOES NOT* violate the conservation of energy
principle which cannot be violated. That notion relies upon
one watt per unit area of total destructive interference
occurring somewhere else. The one watt of destructive
interference causes a flat black area. The energy from that
flat black area is redistributed to the area of constructive
interference and causes that area to be twice as bright as
the average area. Born and Wolf's equation is valid.

Itotal = 4I1 where I1 = I2 = 0.5W

2 watts/unit-area = 4(0.5) watts/unit-area

Again, I ask you to please cease from trying to twist my
words into a violation of the conservation of energy
principle. If you think I have uttered such words, you
are mistaken. Next time you are confused, instead of your
arrogant ASSumptions, please just ask me what I meant.

> sine waves.

Tom,

Something else that follows from the derivation is that whilst the indicated Pf and Pr do not have stand along meaning, Pf-Pr does have meaning irrespective of the nominal R for which the instrument is calculated.

For example, if we cascade a 100W source, 50 ohm directional wattmeter, a 75 ohm directional wattmeter and a 100+j0 load, the instrument readings should be:
- 75 ohm: Pf=112.4, Pr=12.4, P=100
- 50 ohm: Pf=104.1, Pr=4.1, P=100

This of course assumes that the instruments do not significantly disturb the thing they are measuring, in this case the V/I conditions at the 100 ohm load.

So, while you can nominate any reference Zo for a Pf or Pr value (and so vary those values), the power passing the instrument (Pf-Pr) is indicated correctly irrespective of the calibration R.

(The article explains that the result of Pf-Pr is only meaningful if the calibration impedance is purely real.)

Owen

-- Assuming lossless line, 50W of course; 50V@1A at the load.

> Where does Pref2=50W go?
-- Into satisfying the boundary conditions at the generator
to line interface. We have way to little info to
determine if the generator dissipates more, or less, or
the same, as if it were terminated in 291.4 ohms.

> Are there ghosts?
-- Some people believe in them. I've never seen on--Oh not
THAT kind of ghost. Well, not at the load, but certainly
at the generator, if the generator is putting out a signal
that's an interesting enough function of time. TDRs really
do work.

> What is the magnitude?
-- Of what? We have enough info to resolve Vf, If, Vr and Ir
on the line, and if we knew the line length and
the excitation, we could be a lot more definitive about
things, but since steady-state excitation doesn't
produce ghosts... but the reflection coefficient at the
line-load interface is -1/sqrt(2), so that's the voltage
ratio we'll see between the forward and reverse waves.

> What power would the generator emit if the line was terminated
> with 291.4 Ohms?
-- "100 watts, of course." For those who don't immediately see
that, it's not difficult to go through some math to show that
the power delivered to a load is independent of the load
impedance so long as magnitude((Zload-Rgen)/(Zload+Rgen)) is
constant--that is, so long as the magnitude of the reflection
coefficient is constant--as it is along a lossless line...

and from that, find the Thevenin or Norton equivalent of the
source in this example ... and from that, figure the power
that source will deliver to a matched load.
>
> Please do not modify the example for analysis since this may change
> the results.
>
> There is much to be learned by trying examples that may challenge
> your expectations.

:-) This reminds me of some thoughts I posted a long time ago about
lines whose Zo is somewhat reactive. For example, if a linear
sinusoidal source of impedance Zo is connected to a line also of
impedance Zo, what load maximizes the power in the load? If you keep
magnitude((Zload-Zo)/(Zload+Zo)) constant, is the power dissipated in
the load independent of the phase angle of (Zload-Zo)/(Zload+Zo)?
>
> ...Keith

>
> What is a "Virtual reflection coefficients"?

SQRT(Pref/Pfor) which often differs from the
physical reflection coefficient (Z02-Z01)/(Z02+Z01)

Here's an example:

100W---50 ohm line--+--1/2WL 300 ohm line--50 ohm load

The virtual reflection coefficient looking into point
'+' from the source side is SQRT(Pref/Pfor) = 0

The physical reflection coefficient looking into point
'+' from the source side is (300-50)/(300+50) = 0.7143

The virtual reflection coefficient is an effect. The
physical reflection coefficient is associated with
the causes of reflections. The S-Parameter reflection
and transmission coefficients are physical. There
are *always* reflections at a physical impedance
discontinuity but they are often zeroed out by
wave cancellation.

So, what you are referring to with the term "virtual reflection
coefficient" is the magnitude the reflection coefficient (rho). or |(Z02-
Z01)/(Z02+Z01)| (Gamma).

Did you get that usage from an optics text?

I haven't seen "virtual reflection coefficient" used to have that
meaning. Nor have I seen hams commonly, as you suggest, using rho in the
way in which you could use S parameters or Gamma.

I did note that in a Google search, more than half the relevant hits on
the first page were your writings, so it is clear that you use the term.

It's feed at the bottom.

The coil description should be inductance not impedance.

I am handicapped by being away from my reference books
but I believe that RF engineers use rho and Gamma
interchangeably along with other symbols like RC.

The difference between a virtual reflection coefficient
and a physical reflection coefficient has nothing to
do with what it is named. No matter what is the value
of the physical reflection coefficient, e.g. s11, the
virtual reflection coefficient at a Z0-match is zero
because the reflected voltage, current, and power is
zero.

Are you sure there are different rules for ham radio sources
than for all the other ones? Something different about them?
Something that makes them not amenable to the techniques used
for others?

If that is so, I am surprised at your claim that ham radio
sources have something in common with light bulbs and lasers
such that knowledge of those subjects can help analysis, while
any knowledge of the behaviour of other electrical circuits is
for naught.

Seriously though, it does all work. The problems are solvable.
You don't need to throw up your hands and say: "too tough."
And then rationalize this response by calling them "too
different" or saying "insufficient information".
Much can be learned by solving the problems set using more
controlled examples. Try it. Using the regular techniques will
produce the same answer for all the problems you can currently
solve, as well as allowing you to solve ones you currently
declare as unsolvable.

I believe the following web page is indicative of
how Gamma has essentially been replaced by rho.

http://www.ac6la.com/stss.html

The ARRL Antenna Book implies that rho is used
by amateur radio operators while Gamma is still
used in some professional circles.

Hmmmmmm. I'll have to think on this. Perhaps after I work out whether
the source impedance of a properly tuned amateur transmitter is the
complex conjugate of the load impedance.

You are using the rules of superposition in your examples.
I don't know if the rules of superposition apply to those
other sources but I do know that a ham transmitter, like
my IC-706, is not linear enough to abide by the rules of
superposition. How is superposition supposed to handle
foldback?

Ham transmitters cannot willy-nilly be shorted and opened
in order to ascertain their linear model characteristics.

A signal generator equipped with a circulator load solves
all the experimental problems but doesn't act like a ham
transmitter.

> Seriously though, it does all work. The problems are solvable.

If that is true, why hasn't anyone ever solved them,
published the results, and ended the arguments? The
"solutions" produce different results depending upon
whose brain is being used. Nobody has ever *solved*
the problem and therefore the argument still continues
to rage.

I see no connection between what you have posted above and what
you posted below.

Above: Itotal = 4I1
Below: nothing with a factor of 4

Above: 100 + 100 becomes 400
Below: 200 + 200 becomes 400
but then you compute a 100 and claim some relationship

> Absolutely NOT! There is 200 watts of destructive

Now once again you have assumed that there are only positive roots.

> On the source side of point '+':
> P3 = Pfor1(rho^2) = 100W
> P4 = Pref2(1-rho^2) = 100W
>
> P3 + P4 - 2*SQRT(P3*P4) = Pref1 = 0W
> (200W of destructive interference)

And positive roots here again, but this time it is subtracted.
Isn't that the same as adding the negative root?
So the two equations are identical, they just use the different roots.

But how do you know which to use?

Enquiring minds...

No, above: 100 + 100 + 2*SQRT(100*100) becomes 400
That's the nature of constructive interference.

There is 200W of destructive interference on the source
side of the Z0-match which is supplying the 200W of
constructive interference on the load side.

> Now once again you have assumed that there are only positive roots.

Since there is no such thing as negative power, the negative
root is discarded as not representing reality. The sign of
the interference comes from cos(0) for constructive interference
and cos(180) for destructive interference.

That particular sweep seems to be from a highrise building which had hex
crimp connectors every 25 feet all the way up the building. A single
hex crimp, or a bunch of hex crimps spaced irregularly, would have far
less effect. So whether this matters partly depends on whether you're
wiring an apartment building or just a house.

With all due respect, that's a rather frightening position to maintain. I've had to replace both .750 and .500 because of dings. Complaints were that certain channels were out. A couple of years ago I had to replace a 4 foot piece of RG 6 inside a wall (splitter to outlet) that had the attenuation of a 100 foot cable. 950MHz to 1450MHz worked (though not near as well as it should have), but the rest of the bandwidth up to 2200MHz didn't work at all. Electricians had greatly exceeded the minimum bend radius when they made up the outlet.

DC does not necessarily mean that RF will work, nor does RF necessarily mean that DC will work.

Jimmie
I can assure you I don't do that sort of careless nonsense. I can also assure you that whenever I'm involved before the foundation is poured or at least prior to it being back filled there will be no driven rods on that job. They are the single least effective electrode you can install. When I have to install driven rods, such as for a heavy up, I will stack them using rod couplers until I'm under twenty five ohms and perform a witnessed test for the inspector. I consider eight foot driven rods a complete waste of time. Mind you I'll install them when I'm forced to but you will usually find mine driven through the bottom of a three foot deep trench on at least twenty feet of bare copper number two AWG grounding electrode conductor.

As for the US NEC being a minimum standard that is not always true. In at least ten states it is both the minimum and the maximum standard that a public electrical inspector may apply. So called "min max" states do not allow the local governments to amend the US NEC. Were the US NEC is the minimum standard you have to use underground metal water piping as a grounding electrode whether or not it jibes with your religious beliefs

about what constitutes an electrode or not. If you were bonding the plumbing you could do that with a conductor sized for the largest branch circuit supplying an appliance that is attached to the plumbing. When you are using the piping as an electrode you must size the conductor to the size of the service entry conductors. People like W Tom cannot bring themselves to admit that underground metal water piping is an effective grounding electrode and worse still that it more effective then most of the other electrodes listed in the US NEC at least in homes. I always check the impedance of my grounding electrodes and that's what the measurements say to me.

Dear Wim PA3DJS:

How I wish that I could read Dutch. However, in looking over all of
your work, it continually occurred to me that much of the base of English
comes from Northern Nederland.

I looked at the first table on page 20 of your work. The information so
intrigued me that I ran almost the same information through NEC4, which does
well with antennas close to the ground. I assumed: a center frequency of
3.6 MHz, a horizontal half wave dipole slightly adjusted to be resonant at
3.6 MHz at each height, the use of Cu wire 2 mm in diameter, and earth with
a sigma of 0.01 and a relative dielectric constant of 15. This is what I
found without too obsessive an amount of tweaking:

The data is in this order:
height of the dipole in meters
the real part of the dipole's impedance in ohms
(the phase angle of the impedance was kept under 2 degrees)
the approximate SWR=2 BW in a 50 ohm system in kHz
the total apparent loss of the system in dB
(this is found by integrating gain in all directions)
the peak antenna gain in dBi

4.2 38.1 125 6.25 2.0
5.8 37.7 120 4.31 4.1
8.3 42.1 130 2.59 5.8
10.4 49.0 140 1.81 6.5
15 66.5 145 1.04 6.9
20.8 85.7 125 0.7 6.5

Most of my results are close to your results. It is interesting to know if
I used the same assumptions. Please let me know.

I encourage you to consider translating your work, or at least parts of it,
into English.

Ed, I'm sure what you say is true. However, one-off moderate mismatches
(or even repeated moderate mismatches which are buffered by
attenuation), such as might be caused by the use of poor quality
connectors, should not cause a failure of service unless the service
would have been marginal if the connectors were good.

As for bends in cable, if you can, tie a loose knot in a piece of coax,
run a wideband sweep through it, and observe the output. Now pull the
knot tight. Let me know when the output starts to be affected.

Let me say again, I'm not advocating sloppy practices and poor
workmanship. Manufacturers' specs and industry standards should always
be adhered to. This avoids endless truck-rolls (God - I hate that
Americanism!) to the 1% of customers where some bright spark has cut one
corner too many. But, especially in the amateur world, we should maybe
not worry too much about using things which industry has rejected, often
for reasons which have absolutely no impact on what we are trying to do.
So I'm NOT throwing out my stash of crimp and screw-on F-connectors!

Ian.

One of the principles of superposition is that you can apply
it to non-linear systems as long as they remain linear in the
operating range that is of interest.

> Ham transmitters cannot willy-nilly be shorted and opened
> in order to ascertain their linear model characteristics.

Read
http://www.w2du.com/R2ch19.pdf and
http://www.w2du.com/R3ch19a.pdf
for descriptions on how to do so without needing to short or
open the output. These articles argue that at least the
amateur transmitters examined are linear over the operating
range of interest.

> If that is true, why hasn't anyone ever solved them,
> published the results, and ended the arguments?

The problems presented in the examples are solvable and
have been solved in public on this group.

> The
> "solutions" produce different results depending upon
> whose brain is being used. Nobody has ever *solved*
> the problem and therefore the argument still continues
> to rage.

The continuing argument is more a reflection on the people
involved than on the problems. For the most part, the various
approaches produce the same answer to the questions, except
that some approaches provide no answer to some of the questions.
Those who support those approaches then declare those questions

unanswerable rather than exploring the approaches that do answer the questions.

An interesting question is why do people reject the approaches that work without examination? I am sure that there must be some opportunities for psychological study there.

I'm leery of the concept of propagating power (especially after seeing the morass it's led its adherents into), but most certainly negative power is the time rate of movement of energy that's going the other way. If we make a simple circuit of sine wave source and load where the load is anything but pure resistance, we can see that the energy goes one way for part of the cycle, the other way for the rest of half the cycle, then repeats the movement in alternate directions during the second half of the cycle. The powers (observed at a single point) during the movement in the two directions are positive and negative. Which direction of energy flow represents positive and which represents negative is entirely a matter of choice.

The constant mixing of and confusion between power and energy is one of the tools used to keep the discussion's rational participants off balance, and it has been shown to work quite well. A real analysis of energy flow involves calculating the power at various points and times in the circuit or transmission line of interest. This gives a view of energy flow very different from the bouncing waves of average power; flurry of s-parameter gobbledigook; virtual shorts, opens, photons, and reflection coefficients; and vague parallels to optical phenomena that unceasingly issue forth. But the view that comes from calculation is correct, while the alternative is just so much smoke and noise.

> Isn't negative power just power that is going the other way?

That is just a mathematical convention. If we say
left to right is positive, then right to left
becomes negative. If we say right to left is
positive, then left to right becomes negative.
Same for up/down or down/up or 45 degrees vs
225 degrees. It is a purely arbitrary mathematical
convention. True negative power just doesn't exist.
Negative energy would violate the conservation of
energy principle.

Is a Poynting vector pointing toward Alpha Centauri
positive or negative?

Since true negative power is impossible, the negative
power result of a square root process is discarded
as an artifact.

One of the assumptions in your model is that the source
impedance remains constant with varying degrees of
incident reflected energy. That assumption is false for
an IC-706. Variable constant source impedances are not
allowed by the rules of superposition.

> The problems presented in the examples are solvable and
> have been solved in public on this group.

:-) Then publish the results in QEX and settle it once
and for all. :-) I predict that QEX will refuse to publish
your ideas. The problems "solved in public on this group"
are simple-minded and bear no resemblance to reality.
They are akin to: Assume a lossless transmission line.
Therefore: There are no losses in transmission lines.
In classical logic, your "solution" is known as
petitio principii.

> An interesting question is why do people reject the approaches
> that work without examination?

Translation: Why would anyone disagree with me and be
wrong when they could agree with me and be right? :-)

Here's what I said years ago in my energy analysis
article:

"The term "power flow" has been avoided in favor of
"energy flow". Power is a measure of that energy flow
per unit time through a plane. Likewise, the EM fields
in the waves do the interfering. Powers, treated as
scalars, are incapable of interference."

Seems you are still trying to influence people through
false innuendo.

> ... flurry of s-parameter gobbledigook;

There you have it, folks. Everyone give up on your
S-Parameter analysis. It's only "gobbledigook" (sic).

> But the view that comes from calculation is correct, while
> the alternative is just so much smoke and noise.

One wonders why that smoke and noise yields the same results
as your short-cut methods plus the tracking of energy through
the system. Could it be that the wave reflection model is a
super-set of your simplified model?

Roy, one of the questions I continue to ask myself is why certain explanations of transmission line / load behaviour seem inconsistent with basic AC circuit theory as it applies at 50Hz or 60Hz, why the explanations hinge on a restriction that forward power and reflected power are purely real when in the general sense, a load may be reactive and therefore there is real and reactive power at the line-load interface, and similarly, depending on the transformed impedance, the source-line interface.

One can only guess at the motivation for all the obfuscation that we see here. The invention of new terms, multiple meanings for terms, inconsistent properties for entities, switching in and out of optics, photon explanations, changing dimensions of quantities for convenience, construction of special cases to demonstrate assertions and that don't even qualify as inductive inferences, etc, are all part of a vast array of obfuscation.

Thankfully, textbooks are not as confusing.

That's an easy one, Owen. The wavelength is so long at
60 Hz (5,000,000 meters) that the lumped circuit model
usually works just fine. As you probably know, the lumped
circuit model is a sub-set of the distributed network model.
If the lumped circuit model worked for RF, the distributed
network model (wave reflection model) would have been
abandoned long ago.

100m of transmission line is 0.00002 wavelengths at 60 Hz.
Distributed network effects are negligible.

100m of transmission line is 10 wavelengths at 30 MHz.
Distributed network effects are at a 100% level. Current
in the loop is flowing in opposite directions at ten
points around the loop at the same time.

Somewhere in between 60 Hz and 30 MHz, that old patched-up
lumped circuit model must necessarily be discarded.

> One can only guess at the motivation for all the obfuscation that we see
> here.

Sorry, but the actual obfuscation seems to me to originate
with trying to use an inadequate, patched-up, lumped circuit
model on distributed network problems. When the lumped circuit
model yields correct results, the distributed network model
yields the same results. When the lumped circuit model yields
incorrect results, the distributed network model yields
correct results.

Again, the challenge is for you guys to generate standing-
waves in the complete absence of reverse traveling waves.
Until you provide a valid example of that, the reverse
traveling waves continue to exist (in spite of all your
hand-waving). They obey the rules of the wave reflection
model and the principles of superposition and conservation
of energy.

The principle of superposition gives us permission to treat
forward traveling waves and reverse traveling waves
separately and then superpose the results. We get the
correct answer every time.

If you fail at generating standing waves without reverse
traveling waves, then for what you guys say to be true,
you must be able to generate traveling waves that contain
zero energy.

It appears that some people have been using mashed potato
short-cuts for so long, they have lost track of the basic
principles underlying the component wave behavior. Anyone
who believes an S-Parameter analysis is "gobbledigook" (sic)
falls into that category.

Which is, of course, why all my examples explicitly state the
construction of the generator to be one that is guaranteed
linear. But if the behaviour for this kind of simple case
can not be understood, there is no hope for understanding
a real transmitter. The argument "since I can not understand
a real transmitter, there is no value in understanding a
linear generator" seems weak.

I would hope so. The ideas are quite basic, not mine, and can
be found in any standard text book on transmission lines and
circuit analysis. No need to publish in QEX. Or perhaps I
misunderstand QEX's audience and it is appropriate for them.
But then I suspect that more capable writers than myself would
be the appropriate authors.

Have you considered putting optics aside for a moment (after
all, we are trying to understand circuits, especially in the
transmitter), and cracking open any textbook that deals directly
with the subjects at hand?

Dont fasten the antenna to your chimney, Chimneys arent made to handle a lot
of lateral force.

Let's just agree to disagree. We both hold positions based, at least in part, on many years of experiences.

I did not say that hex-crimp fittings WILL cause issues, I said they COULD cause issues.

As for the knot/sweep thing; no need. I have already seen the results.

Welding , I think this antenna got started as a CB gimmick, well maybe not,
The idea is something akin to a cubical quad using plumbers delight
constrction. I built one for CB back in the early 70s because I was afraid
of tackling a quad then. Believe me the quad was much easier to build and I
think it performed noticably better than the delta.

Good point! I live on the coast and I've found aluminum will be the
first to go (about five years or less depending upon the alloy) while
my white unpainted fiberglass held up over 12 years before showing
signs of fiberglass disintegration. When I replaced it with the same
model antenna I spray painted the new antenna with two coats of black
Krylon fusion.

Here's a list of questions for you and everyone else.

1. Is the distributed network model valid? If not,
please explain where it is invalid.

2. Is the wave reflection model valid? If not,
please explain where it is invalid.

3. Is the base of knowledge and laws of physics
from the field of optics valid? If not, please
explain where they are invalid.

4. Is an S-Parameter analysis valid? If not,
please explain where it is invalid.

5. Does the principle of superposition give us
permission to analyze the forward wave and
reflected wave separately and then superpose
the results? If not, please explain why not.

6. Does the conservation of energy principle
work for forward and reflected waves? If not,
why not?

7. Does the label of "obfuscation" really apply
to items 1-6?

8. Do you and other gurus already know everything
there is to know or does every person have holes
in his/her limited knowledge base?

Absolutely???

So if you suspended another dipole above your NVIS dipole and oriented 90
degrees to each other, the difference would be insignificant?
Then move it up into the "clouds", then move down to earth at the distance
and you will see "insignificant" difference in signal levels?

Seems that direction finders should not work according to this "verdict",
Eh?

One thing is the direction of the signals (maximum) another one is the
polarization. Based on the orientation of antennas, one can orient the
antenna to find the minimum signal.

I have no beef with above, and would like to thank you and Walt for
persisting in defending, explaining and trying to correct some "wrongos" out
there.

Seems that the unbelievers are in the same camp with those who could not
digest the behavior of loading coils in standing wave antenna circuit. Seems

it would be much nicer if the discussions were more in the line "oh, yea, why?" rather than "you fool, you know notin'" ...or something like that.

I have experienced special case of interference between two antennas, fed from the same transmitter and separate amplifiers. The result was distorted signal on SSB, seems was a bit wider and modulation being raspy. It appears that part of the "other" RF was picked up by other antenna and amp, "processed" and retransmitted. I have observed this effect on one YU station, alerted him to it, asked to switch one PA-ANT off, and signal became "crystal" clean.
Let the "it can't be" games begin :-)

So it seems that if I want transmit the same signal in two or three different directions- antennas, they should not "see" each other, or they will interfere (until they go through atmo/ionosphere "massaging") and lose their correlating identity?

Thanks Cecil and Walt!

If you remember, two of those gurus tried to use standing-
wave current to measure the phase shift through a loading
coil apparently not realizing that their simple-minded model
wouldn't accomplish that task because the phase of standing-
wave current is essentially unchanging all up and down the
mobile antenna. Last I heard, they were rabidly defending
those obviously flawed measurements because, of course,
gurus know everything and never make mistakes. :-)

Hi Yuri,

As the wave pass through the ionosphere, strange things happen. You could google on Faraday rotation, ordinary and extraordinary waves to find out that at low frequency, the change in polarization is significant.

Based on the down coming wave, you cannot determine the orientation of the transmitting antenna, neither the position with reasonable accuracy (for NVIS propagation).

When you place the receiving antenna just above the transmitting antenna you are right, but we were discussing NVIS propagation.

Best Regards,

Wim

> Again, the challenge is for you guys to generate standing-
> waves in the complete absence of reverse traveling waves.

I do recall a textbook derivation of the voltages and currents
on a trasmission line that used the distributed model and
differential equations. It expressed the result in terms
of x (distance along the line) and t (time). It was messy.

It then followed this with a proof showing that thinking of
the system as having a forward and reverse wave produced the
same result. This was much simpler.

But which one was real?

In the end, it is the actual distributed voltage and current on
the line that are real, not the means of describing them.

Both methods accurately describe these, but I certainly prefer
the latter since I can do the math for it.

Still, just because I like to think of it that way, just because
it gives me the right answers, does not mean that that is the way
it is.

Reality is the distributed voltage and current.

Use the analysis technique of your choice, but only as long as
it gives you the correct answers.

> ridiculous.

That's the interference term, Jim. Hecht, Born, and Wolf
all agree that the interference term can be negative.
Suggest you take a refresher course and alleviate the
ignorance you are displaying for everyone to observe.

Remember that P1 and P2 are Poynting vectors, i.e. power
densities and the negative sign simply denotes the
decrease in power density due to destructive interference.
The negative destructive interference subtracts from the
P1+P2 power and the result of that subtraction can *never*
be negative. The interference term has NO separate existence
aside from the existence of the power density components of
P1 and P2.

Please tell Hecht, Born, and Wolf that they are ridiculous.

2SQRT(I1*I2)cos(A)

That's the third term in equation (15) page 259, 4th
edition of "Principles of Optics".

If cos(A) is 180 degrees, the interference term becomes
negative and subtracts from the I1+I2 sum.

Born and Wolf continue, "... and minima of intensity

Imin = I1 + I2 - 2*SQRT(I1*I2)"

Exactly the same equations appear in "Optics", by Hecht,
4th edition, page 388.

"Imin = I1 + I2 - 2*SQRT(I1*I2)"

Note that I is intensity or irradiance, the dimensions
of which are watts/unit-area, exactly the same dimensions
as the Poynting vectors, P1 and P2 above.

In "Fields and Waves in Modern Radio", Ramo and Whinnery
subtract Poynting vectors that are 180 degrees out of
phase to obtain the net Poynting vector?

>> Since true negative power is impossible, the negative
>> power result of a square root process is discarded
>> as an artifact.
>
> But what is TRUE negative power, and how does it differ from other
> types of negative power? :-)

The sign on a power term denotes a decrease in power level
but never to a negative level. Thus, reflected power subtracts
from the forward power to obtain power delivered to the load.
Destructive interference power subtracts from average power
to allow for constructive interference power. In no case does
the net power go negative.

Well, except for the inability to explain where the "reflected
power" goes in the transmitter. Of course this is not an issue
for carefully selected examples where no "reflected power" reaches
the transmitter. A more general analysis technique would not
require such careful selection of examples.

When I fire up the big russian 3.5KW linear into a high swr, I don't have to guess about where the reflected power is going at the xmitter, the nice red glow on the plates are an excellent indication when they begin dumping unknown amounts of power as infrared radiation ... when I grab the coax (150 ft. run) and feel its warmth, I even wonder about how much power it takes to elevate it's temp!

Yes, it is settled in your own mind. In my mind,
there is certainly a need for forward and reverse
traveling waves without which standing-waves would
not be possible. If you want to deny the existence
of the cause of standing-waves, there is nothing
I can to stop you.

The more general analysis technique tells us that
the moon is 1000 miles away from the earth. I don't
know how far away the moon is but I know it is not
1000 miles away.

Jim Kelley wrote:
> Hint:
> people who write physics books know that power does not interfere.

Please tell that to someone who disagrees with
that statement, Jim, which is not me. Here's what
I said in my years old energy analysis article.

"The term 'power flow' has been avoided in favor of
'energy flow'. Power is a measure of that energy flow
per unit time through a plane. Likewise, the EM fields
in the waves do the interfering. Powers, treated as
scalars, are incapable of interference."

You keep making statements like the above in hopes
someone somewhere will believe that I disagree with
it. Old trick - doesn't work.

I say, *EM WAVES DO THE INTERFERING*. Do you want
to argue about that?

I say, *POWERS ARE INCAPABLE OF INTERFERENCE*. Do
you want to argue about that?

Please, if we are going to argue about something,
make it something upon which we disagree.

> Tom Horne

The point I am trying to make is that the ground system must be sufficent on its own and not need to connect to the buildings plumbing to improve the ground. You should never depend on the plumbing especially on residential work because you can not maintain control of modifications to that plumbing system. Good example is my in-laws home, for years the house connected to the well via 1 inch metal pipe and this was also the ground for the house as it was built in 1974. When the new well was drilled plastic pipe was installed to the new well with no groundwire going back to the well casing. A couple of years later a new HVAC system was installed and when there was an accidental short circuit the well pump was fried. This would not have happened if a proper grounding system had been installed at the house instead of relying on the plumbing. Professionals have a responsibility to idiot -proof there work as much as possible but you know how it is, sooner or later someone makes a better idiot.

The fact that the water pipes may be effective or even better than the installed ground really have nothing to do with anything. Ground sytems are for grounding, Plumbing is for water. Electrians dont do plumbing and plumbers dont rewire homes.

Cecil, you have conveniently clipped the context (as you do), the relevant context being the line-load interface and source-line interface.

Statements in some explanations (by others) like "This clearly proves that reflected power and forward power in a transmission line are both real power, and that no fictitious power, or reactive volt-amperes, exists in either one." seem incompatible with the basic AC circuit theory explanation of a reactive load which must exchange reactive energy with the transmission line over a complete cycle (and the same effect at the source end).

Perhaps it is explained by hopping in an out of the instantaneous and average context, just like switching between lossless lines and lossy lines context with declaration, while actually carrying the analytical simplicity of lossless lines and selectively layering selected aspects of the loss.

BTW, I am not surprised at your dissertation apparently dismissing the distributed impedance model of a line, because after all it is the solution of that model that gives us the classic transmission line equations that you seem to not want to use.

If the distributed network model you favour is the S paramater model, properly applied, it is in fact entirely consistent with the distributed impedance line model because the parameters are derived from the solution to the distributed impedance line model.

Yes. Bird Electronic Corporation has done a good job of this with its
"Thruline" wattmeter for several decades.

Its practice is to measure in a 50-ohm Zo resistive lossless impedance
environment where forward and reflected waves are 180 regrees
out-of-phase. This allows Bird to say:
"Power delivered and dissipated in the load is given by:
Watts into Load = Wforward - Wreflected"

I would not argue with success.

And they don't actually work on NVIS signals unless you use them to
measure elevation, in which case they point fairly high up.
```

You're assuming the ionosphere doesn't rotate the signal (or even render its polarization elliptical). Whether that's happening or not will likely depend on conditions at the time. But if it doesn't, then it doesn't matter which way the antennas are oriented in azimuth so long as they are both oriented the same.

Yep....a GOOD screwdriver with a really high-Q coil will run rings around
most other short antennas. Especially if you use a capacity hat. But
for mobile operation while travelling, that gets a bit bulky and hard to
tame, physically.

No, the Bird wattmeter measures only the average power and only at one point. That's vastly different from what I described, which is instantaneous power as a function of time at many points along the line. A complete analysis of energy flow would include equations for the power as a function of time and position. You're sadly mistaken if you think you're getting this information from your Bird wattmeter.

John, it will never sell to the amateur market... you need a simple,
catchy title. If it is destined for the fiction category, you could offer
an sub title like "How reflections ruined my PA... from a ham who
survived to tell the REAL story", with "Don't let it happen to you"
emblazened in flouro red across the cover.

Seriously, simple explanations are appealing, they provide content for
discussion by experts on-air, whether they are correct or not. Simple
explanations can be good, but incorrect ones are never good.

True. The Bird wattmeter measures average power, the same as any a-c wattmeter, and only at the point of measurement. If the line is lossy, the numbers are higher near the generator, and difference between forward numbers, for example, is an indication of loss between insertion points.

I'm almost certain that I'm out of my league (having read some of the previous replies), but for some reason feel bound to input my 2 cents worth (unsure of equivalent value in the mother country <United Kingdom>).

1). periodicity, as I understand it, is more likely to "suck out" ONE particular channel frequency, not several. On the surface, it sounds more like ingress, or some kind of beat.

2). say what you will about crimp and screw on connectors, but the fact is that I make a living as a "noise / leakage" technician, and replace a LOT of them having tracked them down with a spectrum analyzer. Lot's of home builders and home owners use them because they're less expensive, but not installed correctly. Perhaps a trained and experienced installer can put them on properly, but those are few and far between ..... screw on connectors <especially> SUCK in my humble opinion.

3). I'm wondering about perhaps a "store bought" / inferior brand of splitter that might also have been replaced along with the connectors, or perhaps a cross-threaded, corroded (or otherwise inferior) connection, that might be creating the problem. Though unlikely, might be bad cable (even if it IS new "brand name" wire .... stranger things have happened).

Subtle problem, more info is needed. Ideally, a good tech with the proper equipment could look at it and track down the problem. In here, it's all speculation and educated guesses.

I only have 30 + yrs experience in the cable industry, so I'm apparently the FNG in this thread.

Good luck.

I need to brush up my RF and antenna knowledge, which is always something that I've almost but not quite understood. I've got a few books on the subject (two by Kraus, Electromagnetics and Antennas, and another on RFIC design) but they're often dry academic tomes and it's hard to get a feel for the subject. I'd really like something along the lines of The Art of Electronics for RF. The AofE has a high-frequency chapter but it's a bit too brief (though I ought to go and reread it, it's been a while).

Any recommendations for hands-on books that are relatively easy to read, to give an idea of practicalities as well as theory?

Thanks
Theo

So when signal is reflected, the polarization disappears?

The ARRL Antenna Book.

Among texts, King, Mimno, and Wing's _Transmission Lines, Antennas, and Wave Guides_ is one I find particularly clearly written. The Dover paperback edition (1965) can usually be found at a reasonable price.

Amateur radio, perhaps? In the UK look for publications by the Radio
Society of Great Britain; or possibly some libraries and bookstores have
the ARRL Handbooks.

Hi Oli

Construction method of course depends on the size/freq of the thing. In some cases you can use plumping or electrical conduit fittings . I have also seen muffler clamps used but be careful not to weaken the element too much my drilling. Possibly a muffler clamp bolted to some flat bar which is then attached to the elements with hose clamps. Watch out for dissimilar metal corrosion though..

These loops can also be hung from trees. You may even be able to use PVC pipe as supports if the frequency isn't too low..

I had a double delta some years ago that had two elements arrange bow-tie like off opposite sides of the boom. This reduced the torque stress somewhat as the element from one side mechanically continued to the other.

Cheers Bob

On this, I have to admit, The ARRL Antenna Book is well done ... also,
past editions of the ARRL handbooks can be had for a song in used book
stores ... antenna design in amateur circles is rather stagnant, old
literature can still be utilized.

This is a bit of a non sequitur. So what is it that you really
disagree with in the analyses performed by myself and others?

Just for clarity, an example problem that has been previously
analysed is the following:
A generator with a 450 Ohm source impedance drives a 450 Ohm
ideal transmission line terminated in 75 Ohms. What is the
magnitude of the re-reflected wave at the generator?

I think you object to computing the amount of the reverse wave
that is reflected at the generator by using the source impedance.
More specifically you do not agree that the reflection
coefficient at the generator can be derived using
RC = (Zsource - Zline)/(Zsource + Zline).
Also, you do not agree that superposition applies at the source.

Given this, you then do not agree with the computations of the
quantity of the reverse wave that is reflected at the source which
then invalidates any further analysis.

Have I managed to capture the essence of your disagreement with my and others analyses?

Note that these analyses have been performed without the use of powers or interference so these side issues are not part of this question.

...Keith

I don't disagree with anyone's metaphysics. What
you do inside your own mind is none of my business.
(In my mind, I can still dunk a basketball.)

> This is a bit of a non sequitur. So what is it that you really
> disagree with in the analyses performed by myself and others?

I have told you many times. Bench test measurements
performed over the past 20 years or so prove that it
works only in your mind, not in reality. The source
impedance of a typical ham transmitter remains somewhat
of a mystery during actual operation. The arguments
continue to rage after decades of bench test experiments
and measurements. The pages of QEX are filled with those
arguments.

> A generator with a 450 Ohm source impedance ...

False assumption. That transmitters's source impedance
changes away from 450 ohms just as soon as the reflections
arrive incident upon the source, i.e. the source impedance
is a *variable* that depends upon the magnitude and phase
of the reflected wave. If your source impedance is constant,
it doesn't match real-world conditions.

> I think you object to computing the amount of the reverse wave
> that is reflected at the generator by using the source impedance.

I certainly don't object to your computations but the
results of those computations have been disproved on
the bench using real world ham transmitters over the
past 20 years or so. Your simple mental model doesn't
correspond to reality unless you take some extraordinary
steps which deviate from real-world ham transmitters.
Have you taken the time to review those experiments?

I used to have one of its predecessors, an R5, and it was a pretty
decent antenna. You may have to play with it a bit, jiggling the
sections back and forth to get each band resonant, but otherwise it
should go up nicely.

That works as long as everyone else understands what you
are talking about. Here's a quote from:

http://www.ac6la.com/stss.html

"The SWR meter is only concerned with the magnitude of the
reflection coefficient, but rho is a complex quantity having
both a magnitude and angle. If rho were to be measured at
various points along a transmission line, the magnitude would
be fairly constant but the angle would change depending on
the electrical length of the line at the point of measurement."

And from the "ARRL Antenna Book":

"In some professional literature, Gamma is used in place of rho
to represent the reflection coefficient."

Wes, you must be a professional. :-)

As far as I'm concerned, S11 = (Z-Zo)/(Z+Zo), and is commonly known as the (port 1) reflection coefficient, and Zo = 50+j0 unless otherwise specified -- and |S11| is the magnitude of that reflection coefficient. If I see rho without a definition, I only have its context to go by, and in some circles that's pretty weak and often inaccurate. For other ports of a multiport network, of course, S22, S33, and so forth serve.

Almost all I need to know about a TEM line can be expressed by the set of 2-port S parameters versus frequency for the line. Normal coaxial and open-wire lines come about as close as anything I work with to being true linear systems. However, the two-port model covers only the differential TEM propagation on the line, not the line versus ground: it's not useful for analyzing the "antenna" currents on a line. It also doesn't tell me whether lost power is lost to heating or to radiation, and it doesn't tell me about radiation received by the line. The S parameter set for the line can be referenced to 50 ohms (or any other useful impedance), independent of the impedance of the line. With the S parameter set, I can determine power loss, power transmission, images, ... all the usual things. Of course, it's not the only way to characterize the line, but it's complete and accurate to the extent the line really does behave linearly and that only the TEM propagation is important. The line doesn't even have to be uniform; it can be exponentially expanding, or have ripples in its impedance. If the line isn't uniform, the S parameters won't be able to tell you power dissipation versus distance along the line, but they'll still give you net power dissipation under specified conditions of excitation and load.

Cheers,
Tom

Interesting to me that CM railed at me for complaining that his trivial trumped-up non-real-world example wasn't worth considering, and now he's unwilling to accept an example that IS quite realizable. I can EASILY do it on my bench, though I'd prefer to use a 50 ohm generator and 50 ohm line, and a 300 ohm load at the end of the line. It's certainly no more difficult to get a known output source impedance than it is to get a lossless transmission line, but we talk about lossless lines all the time, to remove an unnecessary complication from our discussions. Since we have to test our generators to insure that they really are 50 ohm sources, I feel quite confident that their source impedance doesn't depend on the load you put on them.

With respect to the output impedance of a transmitter, it may indeed depend on the tuning/loading of the transmitter's PA, likely even the power level it's running, and _maybe_ even on the load impedance you put on the transmitter's output terminals. But what I do doubt is that it _changes_ for a given setup including a given load impedance, and in steady state, for sure the load impedance isn't changing. So in steady state, can we determine if there are or are not reflections on a transmission line connected to the transmitter, at that interface? If you can't, how much do you have to disturb steady state to make that measurement?

If battles have raged on for years about the output source impedance of a transmitter, I submit that the people making the measurements either (a) don't understand what they are doing, or (b) have not fully specified the conditions under which they made the measurement, or both. I assume they would't battle if they agreed they measured different values, but that the conditions were also different, but that may not be a valid assumption--some are known to battle regardless.

As I mentioned, we have to be very careful about input and output port impedances in measurement equipment. It's not necessarily an easy thing to get "right," but I'm confident that we've been doing it right, and probably for longer than the "debate" over transmitter

output source impedance has been going on.

If you don't believe there's a solution to the example Keith posted,
you have no right to believe in the results of a measurement with a
vector network analyzer, and you should certainly not trust the
indicated output level of any signal generator.

Cheers,
Tom

What is the length of each of the legs on a condobuster antenna. I know its 37 ft. Is it 37ft/2. or is one leg longer.

So your only beef with my examples is that they do not
accurately model a "typical ham transmitter"?

When you say that source impedance is a "variable", do you
mean this for a "typical ham transmitter", or do you assert
that it applies to every generator, even those which can be
accurately modelled with a Thevenin equivalent circuit (as
many signal generators, even TVSGs can)?

> > I think you object to computing the amount of the reverse wave

Which results have been disproved on the bench?

> Your simple mental model doesn't
> correspond to reality unless you take some extraordinary
> steps which deviate from real-world ham transmitters.
> Have you taken the time to review those experiments?

Are the experiments documented in Reflections chapter 19 and
19a representative examples?

My read of these chapters is that they offer compelling
argument and evidence (at least for the tube style

transmitters examined) that ham transmitters are linear*,
at least over their normal region of operation.

Is it your assertion that these claims are incorrect?

...Keith

* Don't confuse this use of linear, which is that the
output stage is linear, with whether the input to output
transfer function of the transmitter is linear. The transfer
function may be non-linear even though the output stage is.

No, mostly the down comming wave has a circular component (eliptical polarization), therefore the orientation is not of significant importance. Wim, PA3DJS.

I'd appreciate any recommendations for an inexpensive Smith chart based program which can be used for the design of basic matching networks and the like. I'm looking for something along the line of MicroSmith or WinSMITH, neither of which is any longer available.

Thanks,
Roy Lewallen, W7EL

>Roy Lewallen, W7EL

Roy, it seems to me everyone has missed an important point concerning a circumferential component of the
current.

We know that the current flowing on the radial wires is radial in direction. What seems to be missed is the
current that returns to earth between the wire radials. That current is going to flow in the direction of the
lowest resistance. As such it's not going to flow radially alongside the currents flowing on the wire, because
the radial resistance of earth between the radial wires is much greater than the resistance of the wires.
Consequently, currents reaching earth between the wires will find a lower resistance by traveling toward the
nearest radial wire instead of continuing in a perfectly radial direction. This new direction of current flow
will not necessarily perfectly circumferential, but will certainly be somewhere between radial and
circumferential.

>[rest removed]

Dear Mac,

Thank you for sharing your results with me. You are fully right, the results are almost the same. The difference with my assumptions is wire diameter only. I used 10mm. I expected more difference in useful bandwidth, because of the factor 5 in wire diameter.

The simulations were carried out on IE3D with a lossy dielectric as ground. The first table on page 17, shows the results for a perfect ground.

I wasn't satisfied with the bandwidth, so the actual antenna consists of 2 wires (1m separation). This gave me sufficient bandwidth to use the antenna without a tuner.

The results between the brackets are with 3 floating reflector wires under the antenna (about 1 m above ground). This gives an evident increase in gain. The gain increases somewhat by raising the 3 wires to about 1.5..2m above ground.

At this moment there are no plans to translate the document into English language. As you have seen, the text in the images is in English language, so you never know what happens during a vacation.....
The birdth of the Dutch version was in Spain.

Best Regards,

Wim
PA3DJS.

Methinks you have missed the context of the discussion.
If the model doesn't work for an IC-706 it is not much
use to amateur radio operators. I have already said that
a valid model can be had for a signal generator equipped
with a circulator load. Now do it for an IC-706.

Hi Owen,

Please excuse the long delay in responding to your post of 4-8-07, 4:26 pm EDT. I have been away from the
computer since then, attending to personal chores that took priority over rraa.

I'm sure your comments weren't meant as a personal attack, and I accept your apology.

However, your consideration of statements appearing in Reflections as flawed on the assumption that the
concepts presented there concerning impedance matching apply only to lossless and distortionless lines, IMHO
is unfair, because it is not true.

For readers of your post who now may be questioning the reliability of statements appearing in Reflections,
I'm working on a more detailed discussion of the issue for clarification that I will enter on the rraa as a
new thread.

Walt

As far as I know, the Bruene/Maxwell argument first saw
light in a QST article in the early '90s and has been
raging ever since.

> My read of these chapters is that they offer compelling
> argument and evidence (at least for the tube style
> transmitters examined) that ham transmitters are linear*,
> at least over their normal region of operation.

Linear is not the requirement for your source impedance.
Constant, fixed, and linear is the requirement for your
source impedance. Nothing you have presented had the
source impedance as a linear variable.

Hi Walt,

So as BL&H report without too much pain:
>>>at page 760:
>>> "When the earth is of good conductivity,
>>> the current leaves the wires and enters the earth closer to
>>> the antenna than it does when the earth is a poor conductor."

Now, as to your comment
>That current is going to flow in the direction of the
>lowest resistance.

It is awfully damned hard to beat the least resistance path of copper
over earth. And yet BL&H offer us this observation I requote above.

What will trump a higher resistance path is greater potential
difference and proximity. Note that BL&H are quite specific about
proximity to the antenna, and hence it follows that the separation
between radials is closer there, than further out from the antenna.
Certainly I can find no where to quote this observation of growing
closeness from BL&H for Roy's consideration, but I trust my common
sense of geometry here too, and I will proceed.

BL&H report (without going into the how, or how much):
>>> "From (8) [that formula] we see that the earth
>>> current proper leads the current in the wires
>>> by 90 electrical degrees."
such that at "that" radial distance, there must exist the greatest
circumferential potential difference between the wire and the earth
currents which is clearly mandated by phase. If a potential gradient
along the circumference is greater than that along the radial, and the
distance along the circumference is smaller than the distance along
the radial; then it stands to reason why BL&H even offer to comment
"current leaves the wire."

Current through earth is largely lost to heat although I do have a
fractal antenna that uses earth current to optimize its low angle
launch characteristics.

Ultimately this reduces to the rather pedestrian observation that more radials closer in serve efficiency - observed and reported by BL&H.

Please don't take this the wrong way, Cecil, but after seeing this response to a fairly inert remark, I'm not feeling comfortable enough to take you entirely at your word.

Perhaps we just misunderstand each other, but I don't know of another way to interpret what you have written. If you don't believe that power interferes, then why else would you continually write interference equations in terms of power? You can't just arbitrarily throw quantities with any units you like into equations, and then claim authoritative references as your source, Cecil. Is it your contention that interference is not a validating pre-requisite for use in an interference equation?

I'm pretty sure somebody using the name Cecil Moore posted Ptot = P1 + P2 +2*SQRT(P1*P2), and used the equation to show how two 100 watt generators generate 400 watts. Help me out. Where did I mess up here?

Hi Wes,

My preferred usage is the same, and for the reason that Gamma and rho can be written directly in html as the greek symbols, and in ascii text as Gamma and rho. The notation that rho is the magnitude of the complex reflection coefficient and that the complex reflection coefficient is written as rho with a bar over it is not conveniently and consistently expressed in a short notation in ascii only media.

If it is declared (as I did in my post) then the usage is fair. The sidetrack onto "standard" notation was just another diversionary tactic from YKW.

Thanks for the suggestions, but I see I need to be more specific about what I need.

I'm looking for a Windows-based program that runs on a local machine rather than remotely as at a web site. The objective is to find a program for EZNEC to write input files for, so that its frequency sweep impedance data can be easily and directly imported into the Smith chart program for visual analysis and to aid in designing narrow and broadband matching networks for antennas. EZNEC originally did this for MicroSmith, then WinSMITH input file writing was added when MicroSmith became unavailable. Now WinSMITH is also unavailable, so I'm looking for another one which I can adapt EZNEC to.

Walt,

I hadn't missed that phenomenon, but didn't mention it because it doesn't produce a circumferential current. If you look at the current flowing from the earth to each radial wire, you'll see that the sum of these currents will be purely radial, assuming that the system is symmetrical, i.e., radials are equally spaced and equal length, the ground is homogeneous, and the radiator is vertical. Consider a bit of current returning between two radials, which is a little closer to the radial on the right. It'll detour to the right, giving it a rightward component as well as an inward radial component. But for every such bit of current, there's another one the same distance from the radial to the left which will have leftward and inward radial components. The radial components are in the same direction (inward) so will add but the circumferential ones (leftward and rightward) cancel, leaving a net radial current flow. You can say that the returning currents bend to the right or left as they propagate toward the antenna base, but not that there's a systematic circumferential current flow -- no current crosses from radial to radial in a clockwise or counterclockwise circular pattern like Richard implied.

I recall reading a paper which showed that connecting radials with circumferential wires actually degrades a ground system's effectiveness,

but I wasn't able to lay my hand on it when I looked.

This topic has been discussed in this newsgroup several times in the
past. In my posting of June 17, 2005 in the thread "Re: Calculating VSWR
from rho and rho from VSWR" you'll find a summary of what I found in use
by authors of 16 different textbooks. As you'll see, if you look it up
at http://groups.google.com, there's no single standard usage.

Personally, my preference is the same as Wes' and Owen's - Gamma for
complex reflection coefficient, rho for its magnitude. But usage is so
varied that it's necessary to explicitly show what the symbols mean
unless it's obvious from the context.

So if there is ANY polarization left how can you claim that is not of
significant importance.
The proof in the pudding is that on any signal one can with any antenna,
especially directional, find the spot where signal is minimal or nulled out.
Nulls are sharp vs. broad pattern, but one has to be aware of them and
understand the difference between the pattern and polarization.

I forgot I did make one rotatable delta beam befor this one, sort of a
prototype. It was made of wood and wire. The wire was supported by
bamboo poles.The bamboo was fastened to a wooden boom with lagbolts.
Cut of the head of the labolt in stick it up the bottom end of the
bamboo and clamp with radiator clamps. This actually worked better
than the all metal one. I let my friend have it after I made the metal
one, should have kept this one. He had it up for 4 or 5 years before
the boom finally broke. Im sure it would have lasted a lot longer if
the wood had been varnished.

Hi Roy,

Darn, sorry that WinSMITH is no longer available. Hope you'll
continue to support that format for those of us with that program.
Based on what I just found, I don't have any reason to quit using it.

You might try LLSmith from
http://tools.rfdude.com/RFdude_Smith_Chart_Program/RFdude_smith_chart_program.html.
I don't like it as much as WinSMITH, but it looks like it does
somewhat similar things. I found it via a Google search, which led me
among other places to http://www.sss-mag.com/smith.html and
http://www.circuitsage.com/matching.html. The latter one provided the
link to LLSmith. I think I have a useable version of Motorola's Smith
chart program somewhere, but the version I just downloaded is pure
garbage from my point of view; it may work but it's so awkward that
it's worthless to me.

Cheers,
Tom

Additional comment: if you write impedance files in standard network analyzer format, they can be used by a lot of programs. I believe you can find fairly detailed descriptions of the .s1p format on the web. In particular, RFSim99 can read such files and use them in a 1-port representation. It will even do an automatic L match to an impedance, and will display S11 on a Smith chart. (But I'm remembering a problem if you write them in dB format, something about that RFSim99 uses 10^(dB/10) instead of 10^(dB/20) to convert them to linear before it uses them...)

Cheers,
Tom

OK, I gotta quit looking at Smith chart stuff...

Are you sure WinSMITH is no longer available? See http://www.scitechpub.com/WinSmith.htm.
Looks pretty current to me. My 2.0 version was provided on floppy,
and I see they've gotten into the 21st century and have it on CD-ROM.

Cheers,
Tom

Not all screwdrivers are the same though.. Some are pretty close to
a bugcatcher as far as efficiency. Some are horrible due to excess
coil loss. In general, a screwdriver will usually be one notch down
from
a bugcatcher, which I consider king of the hill. The bugcatcher is
often better due to it's often better coil location. Most screwdrivers
have the coil fairly low, which limits them as far as current
distribution.
I don't use transformers to match per say.. I usually use an
inductor,
and this inductance can be included with the main lumped loading coil.

>
> A whip and auto tuner at the base of the antenna, on the other hand,

> when you consider the mismatch from only having one adjustable device,
> and besides, the dominant efficiency issue is going to be from having
> a physically short radiator on lower frequencies, which is the same
> regardless of how you tune it.

The screwdriver is likely to be much more efficient than the tuner/
whip.
The efficiency is most certainly not the same for a given size whip.
A tuner/whip is likely to be 10-12 db down from a good bugcatcher,
or high quality screwdriver.
The current distribution through the whip effects the efficiency
greatly.
If you feed a whip with a tuner, maximum current is at the tuner.
If this tuner is in the car, maximum current is in the car with you.
A center fed antenna will be a good bit more efficient than a normal
base

fed for a given short height.
The tuner/whip can do semi ok on the higher bands, because it doesn't take much there to begin with. On the low bands, they will be fairly horrible.
Anyway, as far as the OP, the screwdriver would be much better, as long as it's a decent screwdriver. Some screwdrivers have lousy coil design, some don't.

Source record: 43020

Jim Kelley wrote:
> Perhaps we just misunderstand each other, but I don't know of another
> way to interpret what you have written.

Yes, you do, Jim. You know that I agree with you on almost
every technical point yet you incessantly try to erect
straw men so you can knock them down. You are almost
always trying to discredit someone who agrees with you.
To that unfair tactic my response is:

From: "An Energy Analysis at an Impedance Discontinuity in
an RF Transmission Line", by W5DXP, WorldRadio, Oct. 2005

"Single-source RF energy in a transmission line and laser
light are both coherent electromagnetic energy waves that
obey the laws of superposition, interference, conservation
of energy, and conservation of momentum."

"The term 'power flow' has been avoided in favor of 'energy
flow'. Power is a measure of that energy flow per unit time
through a plane. Likewise, the EM fields in the waves do the
interfering. Powers, treated as scalars, are incapable of
interference. Any sign associated with a power in this paper
is the sign of the cosine of the phase angle between two
voltage phasors."

> If you don't believe that power
> interferes, then why else would you continually write interference
> equations in terms of power?

Because that's what Dr. Best, Hecht, and Born and Wolf do.
Intensity, irradiance, and Poynting vectors are *power*
densities. Multiply the following intensity-irradiance
equation by unit-area and what do you get? Why, you get
WATTS of power!

Itot = I1 + I2 + 2*SQRT(I1*I2)cos(A) in watts/unit-area

Multiplying both sides of the equation by unit-area

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(A) in watts

I assume that's how Dr. Best came up with the equation.

Or don't even multiply by unit area - just use Poynting
vectors instead where each P above is a Poynting vector.
The dimensions of a Poynting vector are identical to
the dimensions of irradiance and intensity.

> You can't just arbitrarily throw
> quantities with any units you like into equations, and then claim
> authoritative references as your source, Cecil.

I have not done that, Jim. The Poynting vector has exactly
the same units as intensity and irradiance. Multiply both
sides of the equation by unit-area and the result is WATTS,
the unit of power and that's fully consistent with the
rules of mathematics.

> Is it your contention
> that interference is not a validating pre-requisite for use in an
> interference equation?

The question appears to have a trivial answer so it must
be just another straw man. Yes, interference exists if
interference exists and interference doesn't exist if
interference doesn't exist. Satisfied?

> I'm pretty sure somebody using the name Cecil Moore posted Ptot = P1 +
> P2 +2*SQRT(P1*P2), and used the equation to show how two 100 watt
> generators generate 400 watts. Help me out. Where did I mess up here?

False so just another straw man. I said two 100 watt generators
do *NOT* generate 400 watts because there is no interference
between the generators. Maybe you need your glasses changed?
I did follow that posting up showing how two 100 watt *waves*
can engage in total constructive interference and obtain a total
of 400 watts.

Even you should be able to figure out how two 100 watt generators
can be made to produce a forward power of 400 watts in a
transmission line with an SWR of 5.83:1 and that is perfectly
consistent with Hecht, and Born & Wolf's intensity equations.

****
HECHT AND BORN & WOLF'S TOTAL CONSTRUCTIVE INTERFERENCE EQUATIONS
ASSUME THERE IS AN EQUAL MAGNITUDE OF TOTAL DESTRUCTIVE INTERFERENCE
OCCURRING SOMEWHERE ELSE TO SATISFY THE REQUIREMENTS OF THE
CONSERVATION OF ENERGY PRINCIPLE. For every total constructive
interference equation I1 + I2 + 2*SQRT(I1*I2), there exists a
total destructive interference equation I1 + I2 - 2*SQRT(I1*I2)
The destructive interference and constructive interference
always sum to a net power density of ZERO such that the AVERAGE
power always remains the same.
****

Let's say we have two light waves of 100 watts/cm^2 intensity
and we cause them to interfere constructively. Here's the
intensity equation for total constructive interference.

I1 + I2 + 2*SQRT(I1*I2) = 100 + 100 + 2*SQRT(100*100) = 400 watts/cm^2

Multiply both sides of the equation by cm^2 and you get
400 watts of power and indeed that square cm would be
getting very warm. Somewhere else exists a square cm
with zero intensity.

That is Born and Wolf's equation (16a) on page 259 of the 4th
edition of "Principles of Optics). The equation is correct
and the dimensions are correct. It is also Hecht's equation (9.15)
on page 388 of the 4th edition of "Optics". Those authors all label
the 2*SQRT(I1*I2) term as the *interference term*.

Let's say we have two RF waves or 100 watts/cm^2 intensity and
we cause them to interfere constructively in a coax transmission
line with a cross sectional area of one square cm.

P1 + P2 + 2*SQRT(P1*P2) = 100 + 100 + 2*SQRT(100*100) = 400 watts/cm^2.

With those dimensions, the intensity equation and the Poynting
vector equation are EXACTLY the same. This is equation 12 from
Dr. Best's QEX article, "Wave Mechanics of Transmission Lines,
Part 3: ..." in the Nov/Dec 2001 edition. The fixed cross sectional
area of the coax is redundant and we can choose to deal entirely
with watts.

Hi Roy,

There is a very slick one Switzerland:
http://www.fritz.dellsperger.net/downloads.htm
from Dr. Fritz Dellsperger.

It, like your software, has a free but limited use. Getting the full
use one is rather more obscure as there is nothing mentioned at his
site as how to get a key or otherwise obtain full use (more than a
limited number of points). Somewhere, there was the suggestion of
accommodating a user if they emailed, but that never worked for me.

The only problem with this statement is the assumption that
the result can only be achieved with a circulator. It only
takes a 10 cent resistor. You really should put down your
optics books for a few hours and crack open a basic circuit
theory or transmission line text. Or google, "'lattice
diagrams' reflection". For matching at the source,
only 10 cent resistors are used.

So when a poster presents a problem in a context other "typical ham transmitters", why do you dispute the answers. If you can't discuss the problem in the context presented by the poster, why not have the courtesy to stay out. Others may be interested in learning about how things relate in contexts other than "typical ham transmitters". Why sabotage the discussions by arguing and arguing and then saying "Oh, I only meant my comments in the context of "typical ham transmitters" WHICH WAS NOT THE CONTEXT OF THE PROBLEM STATEMENT. And kindly stop using the Texas A&M example of TVSG and 1000 feet of line. It is clearly out of your context of "typical ham transmitters".

Perhaps, in your dissertations on optics, it would be valuable to state that they apply only in the context of "typical ham transmitters". This might make it clear to the reader that your suggestions are not generally applicable and could reduce the wasted bits.

No indeed, the source impedance was a constant and resistive
in all my examples. That meets the needs for linear analysis.
Remember f(a+b) = f(a) + f(b)?

You are claiming that for "typical ham transmitters" the
source impedance is undefinable. This is quite at odds with
the exposition in Reflections chapters 19 and 19a. Or maybe not,
after all, Reflections is quite precise and claims only for a
specific class of ham transmitters, which, I suppose, may not
be typical. Though they look so to me.

So I take it that you no longer agree with the analysis presented
in Reflections 19 and 19a. I am pretty sure that you have stated
agreement in the past.

It would be valuable if you were to expand on the reasons for your
change of thought. What convinced you that "typical ham transmitters"
could not have their source impedance measured?

Those statements are generally about lossless lines where the
Z0 is purely resistive. In the lossless wave reflection model,
there is no reactive energy in the transmission line. The forward
voltage is in phase with the forward current and the reflected
voltage is 180 degrees out of phase with the reflected current.
Both V*I*cos(theta) terms are in watts with zero vars. Of course,
real world transmission lines have (hopefully negligible) vars.

It is NOT the distributed impedance model to which I object. It is
the lumped circuit model which assumes the speed of light is infinite
and 75m loading coils don't occupy any space. Here's a quote from an
IEEE white paper at: http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

"Consequently, lumped element circuit theory does not (and cannot)
accurately embody a world of second order partial differential
equations in space and time."

There are two models that can accurately describe the same
phenomenon: the power folk like VAs, Watts and VARs; the RF folk
like forward and reverse travelling waves. But the phenomenon
is the same. One can indeed describe what happens on a transmission
line in terms of VAs, Watts, and VARs and any line that has a
reverse wave will be found to have VARs. The different terms apply
to different models, not to different situations.

Just another reason why you have to be careful when you think
that the forward and reverse waves necessarily represent real
power. Trust the power folk on this one; they know what represents
real power, they are billing for it. And its Watts. Net. They
only power that counts is the power you can bill for.

Please stop putting words in my mouth. I have never stated
agreement or disagreement. It is just one possibility out
of many that have been presented over the years. The fact
that there are so many theories is proof that it has not
been settled. Why don't you whip out an article that settles
everything and see what QEX thinks about it?

> It would be valuable if you were to expand on the reasons for your

:-) :-) :-) Uhhhhhh Keith, the power company does NOT bill
you for "Watts. Net." They bill you for the number of joules
(KWH) that you convert from 60 Hz AC to heat. Where the heck
did you learn your physics?

Last month I converted 3,452,400,000 joules to heat here
at my QTH. That's 0.000002442 cents per joule.

Do you have a list of possible approaches?

Is there any environment in which a 10 cent resistor is the
optimal solution?

> > It only takes a 10 cent resistor.
>
> That is naive in the extreme and makes you sound about
> ten years old. If a 10 cent resistor would accomplish

In my world, the solution is optimized for the problem at
hand: sometimes a circulator, sometimes a resistor,
sometimes feedback and sometimes we just don't care about
matching the source so nothing at all is needed.

Keith, that was indeed my point, that talking of the forward and reflected waves as power waves (or whatever non-phasor term is being used today) and the assertion that those "power" waves are entirely real power (for whatever reasons), and the talk of superposition of these waves (where the examples seem to deal with power algebraicly with sometimes a fudge for phase correction) cannot explain the role of a transmission line as an energy store at any instant, nor the exchange of reactive energy at source and load over time.

If that seems a jumble, it is because this stuff is bandied around without much discipline.

In the same vein, I saw an assertion without sufficient qualification that in a transmission line, 50% of the energy is stored / contained in the electric field and 50% in the magnetic field. Again, general statements from specific cases.

It isn't the special case of a lossless line the causes this, it is the conclusions that are incorrectly drawn from the lossless line or incorrectly applied that are the problem.

If you are trying to quote me, Owen, you are misquoting me.
Exactly what is it about the following excerpts from my
2005 energy article with which you disagree?

From: "An Energy Analysis at an Impedance Discontinuity in
an RF Transmission Line", by W5DXP, WorldRadio, Oct. 2005

"Single-source RF energy in a transmission line and laser
light are both coherent electromagnetic energy waves that
obey the laws of superposition, interference, conservation
of energy, and conservation of momentum."

"The term "power flow" has been avoided in favor of 'energy
flow'. Power is a measure of that energy flow per unit time
through a plane. Likewise, the EM fields in the waves do the
interfering. Powers, treated as scalars, are incapable of
interference."

Source record: 43036

Dear Wim:

Thank you for the additional information. The information fills in the rest of the story.

Before I shut down the dedicated computer used for the calculations, I looked at the last entry again. The 20.8 m high dipole in a 50 ohm system seemed to have significantly smaller BW than what you reported. I changed the impedance to 85.7 ohms and then found (using the same data) that the SWR=2 BW is about 250 kHz. With a 1.3:1 turns ratio transformer, this is also the expected BW that would be seen in a 50 ohm system.

In short, my reported BW numbers may need qualification. It is interesting to see how two different simulation techniques reach similar conclusions. I too expect that increasing the wire to 10 mm has little effect.

Vacations can be very creative times. Thank you for your work. 73,
Mac N8TT

Roy
Here is the URL for WinSMITH from Sci Tech Publishing at $125 their price.
Dave Foreman

http://www.scitechpub.com/WinSmith.htm

winSMITH 2.0 automates the graphical solution of transmission line and lumped element matching networks. It is also an excellent training aid for RF and microwave circuit design.

The power of the Smith chart is the ability to present complex data visually, making possible informed judgments regarding transmission line systems, measured data, antennas, matching and other networks.

winSMITH simplifies the process by replacing the paper chart, a pencil, compass (and eraser!) with computerized screen graphics. It offers the speed, accuracy, and repeatability provided by the personal computer and instantaneous data readout in multiple formats. This program is for Windows 98 and XP.

Source record: 43038

Thanks, everyone, for the info. I'm surprised and glad to see that WinSMITH is available again. It was offered first by its publisher, Noble, then later by the ARRL. I'm quite sure there was a period after the ARRL dropped it when it wasn't available. There are some things about it I and others don't like, particularly the 15 step limit to imported impedance data. But EZNEC currently writes files compatible with the "current" (1998) version of WinSMITH. It's apparent, though, that it won't be updated, so it's a good idea to locate a substitute anyway. I've downloaded the Swiss program and will look over the others you've been kind enough to recommend. Thanks again.

Well, I'm not sure that's the ONLY problem with it, Keith! ;-)

Whether the model works for me with an IC-706 will have to wait till someone sends me an operating IC-706 to test. (They should not expect its return...) But I can assure you that whether it does or not, it's a VERY useful model to me, and I am an amateur radio operator. I certainly do NOT accept that the context of this thread is amateur transmitters--there's been so much basenote drift by this time that practically anything relating to vector addition of signals seems fair game.

Cheers,
Tom

PS--know any circulators that work over a range from 10kHz to 6GHz??
Know any that work at 10kHz even?

"In the same vein, I saw an assertion without sufficient qualification that in a transmission line, 50% of the energy is stored/contained in the electric field and 50% in the magnetic field. Again, general statements from specified cases."

Now we accept that energy travels a guided path as an EM wave. The electric and magnetic fields of a wave alternately contain the energy of the wave. When the electric-field is at its maximum, the magnetic-field is at its minimum, and vice versa.

The change in one field induces the other field and vice versa. Thus it is the same energy which is being passed back and forth between both fields. Therefore, over a prolonged period, 50% resides in each field.

Richard, "over a prolonged period" is a qualification, and still it doesn't sufficiently qualify the statement for it to be true.

Granted, the thread drifted away from the subject line
which has little to do with transmitters, but amateur
transmitters are what the entire Maxwell-Bruene
brouhaha is all about.

We already have a special case where a signal generator
plus circulator yields everything we need to know. One
more special case doesn't add much even if it works
which is questionable.

We do not have a valid generalized case that covers
amateur radio transmitters. IMO, that's what the
brouhaha is all about.

In addition:
Assuming ideal TEM waves, the B-field (magnetic) is always
orthogonal to the E-field (electric) and both are orthogonal
to the direction of travel. The power associated with the
ideal TEM wave is ExB in watts (no vars). A TEM wave travels
at the c' = c(VF) speed of light and cannot travel at any other
speed. If it slows down or stops, it is not longer a TEM wave
and has necessarily been converted to some other form of energy.
Energy "sloshing" back and forth between reactances is NOT TEM
energy.

The principle of superposition gives us permission to treat
the forward traveling wave and reverse traveling wave separately
and superpose the results. Superposing the results does NOT
change the nature of the TEM waves. The fact that the net total
fields are no longer orthogonal gives the illusion that there
exist vars in the circuit but they are only virtual vars based
on virtual voltages and virtual currents. There are no vars in
ideal TEM waves in ideal lossless purely resistive Z0 transmission
lines. The forward traveling wave TEM fields have no effect on
the reverse traveling wave TEM fields as long as a physical
impedance discontinuity is not encountered.

Hi Owen,

Please excuse the long delay in responding to your post of 4-8-07, 4:26 pm EDT. I have been away from the
computer since then, attending to personal chores that took priority over rraa.

I'm sure your comments weren't meant as a personal attack, and I accept your apology.

However, your consideration of statements appearing in Reflections as flawed on the assumption that the
concepts presented there concerning impedance matching apply only to lossless and distortionless lines, IMHO
is unfair, because it is not true.

For readers of your post who now may be questioning the reliability of statements appearing in Reflections,
I'm working on a more detailed discussion of the issue for clarification that I will enter on the rraa as a
new thread.

Walt

Maybe not the best words, but they are true in the practical case. In an EM-wave, energy is being passed back and forth netween the electric and magnetic fields on a periodic basis. At any given instant most of the wave`s energy may reside mostly in one field or the other at a given point. Half a cycle nas no practical significance among a million or more.

Perhaps instead of asking Owen to point out what is wrong with
your writings, he would be more comfortable discussing his
theory, given the Vr and Ir terms that he uses, of how the
energy associated with that Vr and Ir wave gets its direction
and momentum changed at a Z0-match when Vr and Ir are
canceled/re-reflected/redistributed.

Message-ID: <736bc$461fa657$d0660f9a$19110@FUSE.NET>
Source record: 43051

This is a question I posted a little while back on
rec.radio.amateur.satellite, but never received any response, maybe because
there is not a good answer. But here it is again:

I like to try to make occasional satellite contacts, usually on VO-52, and
have a place for only one antenna. In the past I have used a dual band
Diamond X-50 vertical, but now I am wondering if something like KU4AB's dual
band
E-factor horizontal loop might be a better choice. Any opinions?

Thanks.

Owen Duffy wrote:
> If the distributed network model you favour is the S paramater model,
> properly applied, it is in fact entirely consistent with the distributed
> impedance line model because the parameters are derived from the solution
> to the distributed impedance line model.

Given that the S-Parameter analysis is valid as explained in
HP's Ap Note 95-1 available from:

http://www.tm.agilent.com/data/static/downloads/eng/Notes/interactive/an-95-1/an-95-1.pdf

--------Z01--------+--------Z02--------
a1--> b2-->
<--b1 <--a2

where a1, a2, b1, and b2 are normalized voltages.

The equation for b1 is b1 = s11(a1) + s12(a2)

Given that a1 and a2 are in phase and that b1 = 0
then s11(a1) and s12(a2) would have to be of equal
magnitude and opposite phase thus making the reflected
power |b1|^2 equal to zero. s11(a1) and s12(a2) cancel
each other out. (What happens to the energy in the
canceled waves?)

What do you get when you square both sides of the equation:?

b1 = s11(a1) + s12(a2) = 0 reflected voltage

Since the square of any of those terms yields watts,
If we simplify by replacing complicated terms with symbols:

|s11*a1|^2 = P1 and |s12*a2|^2 = P2 we get:

|b1|^2 = 0 = P1 + P2 - 2*SQRT(P1*P2) = 0 reflected power

These squared (power) terms are all explained in Ap Note 95-1.
The intensity-irradiance-Poynting vector equation can be
derived from the S-Parameter equations. Good thing the S-Parameter
analysis is consistent with Hecht and Born & Wolf, huh?

4288. Analyzing Stub Matching with Reflection Coefficients

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-13 16:37:02 UTC
From: Walter Maxwell <walt@w2du.com>
Message-ID: <qcbv13hck5o5cbedsl5usqemsmb3uhav3l@4ax.com>
Source record: 43054

In the thread 'Constructive Interference and Radiowave Propagation', Owen, on 4-8-07 asserted that my writings
in Reflections concerning the analysis of stub matching procedures using reflection coefficients are
applicable only in cases where the transmission line is either lossless, or distortionless. I disagree, and in
what follows I hope to persuade those who agree with Owen's position to reconsider.

To assist in understanding why my use of reflection coefficients in analyzing impedance-matching circuitry, I
find it useful to include the concept of virtual open- and short-circuit conditions. I realize that some of
the posters on this NB deny the existence of virtual open-and short-circuits. Therefore, I hope that my
presentation here will also persuade those posters to reconsider their position.

While working in an antenna lab for more than 50 years I have analyzed, constructed, and measured hundreds of
impedance-matching circuits comprising transmission-line circuitry using reflection coefficients as
parameters. For example, in 1958 my assignment was to develop the antenna system for the World's first weather
satellite, TIROS 1. The system required an antenna that would radiate efficiently on four different
frequencies in two bands that were more than an octave related. It required a coupling circuit that would
allow four transmitters to operate simultaneously on all four frequencies without mutual interference. After
developing the antenna that also required radiating circular polarization, I then developed the coupling
system, which, pardon my English, utilized several virtual open- and short-circuit conditions to accomplish
the required isolation between the individual transmitters. The entire coupling system was fabricated in
printed-circuit stripline transmission line (not microstrip), with no connectors except for transmitter input
ports and output ports feeding the antenna. Remember, this was in 1958.

Initially I had only a slotted line for impedance measurements during the development stage, but soon after
the PRD-219 Reflectometer became available, invented by my bench mate, Woody Woodward. The PRD-219 measured
SWR and the angle of the voltage reflection coefficient. The magnitude rho of the reflection coefficient was
obtained from the SWR measurement using the equation rho = (SWR - 1)/(SWR + 1), thus the

PRD actually measured
the complete complex reflection coefficient. Consequently, all measurements from then on were in terms of
reflection coefficient.

Keep in mind that I was working with real transmission lines--not lossless lines. There were several
stub-matching circuits, several occurrences of virtual open- and short-circuits, and the total loss through
the coupler at both the 108 and 235 MHz bands was no greater than 0.2 dB. The input SWR at all four input
ports for a run of 12 manufactured units never exceeded 1.05:1 relative to 50 ohms.

Please let me now explain my understanding of virtual open- and short-circuits. These circuits are developed
by interference between two sets of voltage and current waves having reflection coefficients of equal
magnitude and phase differences of 180ï¿½, respectively. Consider these two examples of a virtual short circuit:

1: The input impedance of a lossless half-wave (180ï¿½) transmission line terminated in a physical short circuit
is zero ohms, a short circuit, but a VIRTUAL short circuit because it was achieved only by the interference
between the source voltage wave incident on the input (0ï¿½) and the reflected voltage wave (180ï¿½) returning to
the input after 360ï¿½ of two-way travel on the line and the 180ï¿½ phase reversal at the physical short
terminating the line. The reflected current wave on return to the input encountered no phase change during its
travel, thus the current reflection coefficient is in phase with that of the source current, allowing the
short circuit to occur.

2: The input impedance of a lossless quarter-wave (90ï¿½) transmission line terminated in a physical open
circuit is zero ohms, a short circuit, but a VIRTUAL short circuit because it was achieved only by the
interference between the voltage wave incident on the input (0ï¿½) and the reflected voltage wave (180ï¿½)
returning to the input after 180ï¿½ of two-way travel on the line and the 0ï¿½ phase reversal at the physical open
circuit terminating the line. The current reflection coefficient occurs in the same manner as with the
half-wave line above.

These two examples can be confirmed by referring to any reputable text concerning transmission line theory.

The voltage reflection coefficient at the input of these two transmission lines is 1.0 at 180ï¿½, and the
current reflection coefficient at this point is 1.0 at 0ï¿½. These are the reflection coefficients that would be

found when measuring at any short circuit, no matter whether it is physical or virtual. Consequently, both
physical and virtual short or open circuits placed on a transmission line can cause reflections. Proof is in
measurements performed at various points in the antenna coupler developed for the TIROS spacecraft in 1958.

Now let's examine a specific example of impedance matching with a stub using reflection coefficients, with
more details than I used in the previously-mentioned thread. As I said earlier, I have measured hundreds of
stub-matching circuitry, but for this discussion, yesterday I set up an experimental stub-matching circuit for
the purpose of being able to report directly on the results of current measurements taken on the circuit. The
source is an HP-8640A signal generator, an HP-5328A counter to determine the operating frequency, and the
combination of an HP-8405 Vector Voltmeter and an HP-778D dual directional coupler to form a precision RF
network analyzer.

Because using a 3:1 mismatch the resulting numbers are convenient, I paralleled three precision 50-ohm
resistors to form a resistance of 16.667 ohms, resulting in a 3:1 mismatch on the line to be stubbed. On a
line with a 3:1 mismatch the correct positioning of a parallel matching stub is 30ï¿½ toward the source from a
position of minimum SWR, where the normalized admittance y = 1.0 + 1.1547. Thus, I selected a short piece of
RG-53 coax that measured exactly 30ï¿½ in length at 16.0 MHz, meaning the stub will be placed 30ï¿½ rearward of
the load.

All measurements obtained during the experiment were less than 2 percent in error compared to a perfect
text-book setup. Consequently, rather than bore you with the exact measured values, I'm going to use the
text-book values for easier understanding.

At the 16.667 + j0 load the measured voltage reflection coefficient = 0.5 at 180ï¿½, current 0.5 at 0ï¿½.
At the stub point voltage reflection coefficient of the line impedance = 0.5 at +120ï¿½, current 0.5 at -60ï¿½.
Open-circuited stub 49ï¿½ in length measured separately in parallel with 50 ohms yields voltage reflection
coefficient 0.5 at -120ï¿½, current 0.5 at +60ï¿½. (Keep in mind that in operation the stub is in parallel with
the 50-ohm line resistance at the stub point.)
With stub connected in parallel with the line the voltage reflection coefficient at the stub point is 0.04 at
0ï¿½, current 0.04 at 180ï¿½. (Equivalent SWR = 1.083, and impedance = 54.16 + j0 ohms.)

Summarizing reflection coefficient values at stub point with stub in place:
Line coefficients: voltage 0.5 at +120ï¿½, current -60ï¿½
Stub coefficients: voltage 0.5 at -120ï¿½, current +60ï¿½
Resultant coefficients: voltage 0.5 at 180ï¿½, current 0.5 at 0ï¿½

These two resultant reflection coefficients resulting from the interference between the load-reflected wave at
the stub point and the reflected wave produced by the stub define a virtual short circuit established at the
stub point.

Let's now consider what occurs when a wave encounters a short circuit. We know that the voltage wave
encounters a phase change of 180ï¿½, while the current wave encounters zero change in phase. Note that the
resultant voltage is at 180ï¿½, so the voltage phase changes to 0ï¿½ on reflection at the short circuit, and is
now in phase with the source voltage wave. In addition, the resultant current is already at 0ï¿½, and because
the current phase does not change on reflection at the short circuit, it remains at 0ï¿½ and in phase with
source current wave. Consequently, the reflected waves add in phase with the source waves, thus increasing the
forward power in the line section between the stub and the load.

So how do we know that the virtual short circuit resulting from the interference is really performing as a
short circuit?

First, an insignificant portion of the reflected wave appears on the source side of the stub point, thus, from
a practical viewpoint, indicating total re-reflection of the reflected waves at the stub point.

Second, the voltage in the line section between the stub and load that has a 3:1 SWR has increased relative to
that on the source line by the factor 1.1547, the amount expected on a line having a 3:1 SWR after total
re-reflection at an open or short circuit. This increase factor is determined from the equation for the
increase in forward power on a line with a specific value of SWR, where rho is the corresponding value of
reflection coefficient. The power increase factor equation is power increase = 1/(1 - rho^2). Thus the voltage
increase factor is the square root of the power increase factor. With rho = 0.5, as in the case of the above
experiment, the power increase factor is 1.3333..., the square root of which is 1.1547.

We have thus proved that the virtual short circuit established at the stub point is actually performing as a
real short circuit.

I believe it is remarkable that the maximum deviation of the measured values obtained during the experiment is
less than 2 percent of the text-book values that would appear with lossless elements, and ignoring measurement
errors and tolerances of the measuring equipment. The recognized sources of error are:
1. Tolerance in readings from the Vector Voltmeter
2. Ripple in the coupling factor in the directional coupler
3. Attenuation in the coax
4. The fact that the nomional Zo of the RG-53 coax is 53.5 ohms, not 50, as used as the reference in the
measurements.

My final comment is that I hope I have assisted in appreciating the practical use of virtual open and short
circuits, and that matching procedures can be analyzed using reflection coefficients that are not restricted
to lossless or distortionless transmission lines.

There is not really a good answer for simple sat antennas. You may want to look at the eggbeater types. Also someone was putting together something called a potato masher. It is a variation on the eggbeater. Crossed dipoles about 3/8 wavelength over a ground plane or reflector works ok , but may need to be switched from right to left polorization.

You seem to be implying that there's something different about how these electromagnetic waves change direction compared to other electromagnetic waves. Why is that?

And when powers <sic> are not treated as scalers, then sometimes it's ok to use power in interference equations, but other times it's not - pretty much just depending on whether or not you get the answer you want. And sometimes you have to either add or subtract the amount of power that isn't somewhere else, or else average with zero in order to get the right answer.

All this and more, this week on r.r.a.a.

>circuit terminating the line.
this is the correlationship.

>The current reflection coefficient occurs in the same manner as with the
>half-wave line above.

It is merely the correlation to an existing, physical open without which the VIRTUAL short circuit would disappear. All intermediary apparatus merely maintain the correlation. There is nothing to be disputed beyond that.

>These two examples can be confirmed by referring to any reputable text concerning transmission line theory.
There is nothing to be disputed beyond that.

>The voltage reflection coefficient at the input of these two transmission lines is 1.0 at 180ï¿½, and the
>current reflection coefficient at this point is 1.0 at 0ï¿½. These are the reflection coefficients that would be
>found when measuring at any short circuit, no matter whether it is physical or virtual. Consequently, both
>physical and virtual short or open circuits placed on a transmission line can cause reflections.

And here we get to the nut of the matter - causality. It is already established that either the physical short, or physical open, whose absence would render any correlation invalid, dominates the action. The proof follows the quality of the physical open or the physical short. A poor physical open or poor physical short will never be improved by ANY transmission line mechanics. On the other hand, poor transmission line mechanics will never deliver the action of the best physical short or the best physical open.

>We have thus proved that the virtual short circuit established at the stub point is actually performing as a
>real short circuit.

There is nothing to be disputed beyond that. This is not, however, a proof that the VIRTUAL short (or open) is the cause.

This may appear to be a criticism of semantics (English to some). However, engineering relies on a far stricter degree of meaning than most endeavors. Correlation is not Causality is one particular admonition that comes to mind from the field of logic. It applies here too.

Walt, it seems to me that you have a need to distinguish VIRTUAL from physical for reasons other than the transmission line mechanics of combining loads (or as I distinguished in other threads, routing energies). A VIRTUAL short or open is metaphor, and it is an useful metaphor for describing systems. What I see beyond these examples you have provided are statements (in other discussions) that tend to confer a reality to the VIRTUAL which is obviously a contradiction on the face of it. Other than that, there is absolutely nothing in your published work that is in dispute.

> waves. Why is that?

There is something different but not unusual. We don't often observe wave cancellation of visible light waves because of the problem of getting coherent beams of light perfectly aligned. Yet, we experience RF wave cancellation every time we adjust our antenna tuners for a Z0-match because the perfect alignment of coherent RF waves inside a piece of coax is an automatic given.

Here's a very simple example. The measured forward and reflected powers are given. The source and load impedances are irrelevant and the length of the Z01 and Z02 lines are irrelevant. Any one of these measured values could be unknown and solved for by calculations based on the conservation of energy principle.

```
------Z01------+------Z02------
Pfor1=100w--> Pfor2=200w-->
<--Pref1=0w <--Pref2=100w
```

We have 100 joules/sec incident upon the Z0-match point from the direction of the source. We have 100 joules/sec incident upon the Z0-match point from the direction of the load. Those waves combine to obtain 200 joules/sec toward the load. It is obvious that Pref2 has to change direction and momentum for that condition to exist.

The power reflection coefficient, rho^2, is obviously 0.5 so the voltage reflection coefficient, rho, is just as obviously +/- 0.707, depending upon whether [Z02 < Z01] or [Z02 > Z01}.

The direction and momentum of the Pref2 reflected wave obviously reverses at the Z0-match point '+'. Exactly how does the direction and momentum of the Pref2 wave get reversed? Where are the physics equations for that process that we hams label "re-reflection"? You and others have been strangely silent on that subject preferring to kibitz rather than provide any technical insight.

An exact duplicate of the above conditions would exist with a 100w laser beam traveling through 1/2WL of thin film with an index of refraction of 5.83.

A B
i=1.0 | i=5.83 | i=1.0
100w laser---air---|--1/2WL thin-film--|---air---...
<--Pref1=0w | <--Pref2=100w | <--Pref3=0w
Pfor1=100w | Pfor2=200w--> | Pfor3=100w-->

What happens to reverse the direction and momentum of the internal reflection in the thin film? Hint: Both Hecht and Born & Wolf give the equations for what happens at plane A. And yes, the S-Parameter equations agree 100% with them.

There you go again, Jim, trying to set up a straw man.
I do NOT treat powers as anything except scalars. Any
phase angle that enters into the calculation is the
phase angle between the two voltages associated with
those powers. They are copied directly from Hecht, Born
& Wolf, and the S-Parameter analysis.

Why not, instead of your underhanded, unethical
kibitzing, present your own set of equations that govern
the process that we hams call "re-reflection"?

Hi Walt,

You have tackled a job that some would shrug off as being impossible to accomplish. You have performed an admirable job of bench work demonstrating the lessons of the best text books. Few here go to those lengths, or with such precision and accuracy.

Your tight writing also reveals a mind that still sees the "big picture" and can describe it with sufficient detail for those who would otherwise dismiss the topic as being too vast and complex to comprehend.

I have published my take on that reflection. It is a two
step process involving:

1. A normal reflection from a physical impedance discontinuity
that doesn't account for all the reflected energy since the
physical reflection coefficient is not 1.0.

2. Wave cancellation between two reflected wave components
in the direction of the source results in a redistribution
of that energy in the direction of the load. This accounts
for the rest of the reflected wave energy.

You have objected to step 2 as invalid so the onus is upon
you to provide an alternate explanation. Please post the
governing equations. So far you have refused to do anything
except harp, nit-pick, and kibitz while wildly engaging in
hand-waving. Time to put up or shut up. Please explain the
process of 100% re-reflection of the internal reflected wave.

It was curious that someone would qualify his statement that way to
begin with - "treated as scalars". What's that supposed to imply if
not that there are other ways to treat "powers" <sic>.

Is there, or is there NOT a cosine term in the interference equation?
How can a scalar have a PHASE ANGLE, and how can the cosine term
possibly apply to anything OTHER than the terms used IN THE EQUATION?!!

I wonder if you'd care to comment on the other mathematical techniques
you introduced to the group this week:

Subtracting power that isn't somewhere else from a number that's
apparently higher than it should be in order to get the right answer,
and averaging power with zero as a means for reducing an excessively
large number by a factor of two in order for the answer to come out
right. I'm still trying to parse how neglecting units makes it ok to
use equations as you see fit. $100 + $100 + 2*SQRT($100*$100) = $400
(The third term represents the amount of money that isn't somewhere
else and should therefore be mine.) ;-)

Right. But the question still remains, what is your claim regarding the exact nature of the "redistribution" if NOT reflection from a partially reflective surface?

Hi Jim,

By substitution, EVERYONE knows TIME is money:
24Hrs + 24Hrs + 2*SQRT(24Hrs*24Hrs) = a work week

Hmmm, does time superpose? Can we find two coherent generators of
time? We can certainly find two generators of money like Ron Popiel's
vegamatic or George Forman's diet grill and as anyone can tell they
superpose with a veggie-burger.

Your paragraph above now talks about an EM-wave, my quote was about a transmission line, let me repeat it to save you going back through the posts:

"In the same vein, I saw an assertion without sufficient qualification that in a transmission line, 50% of the energy is stored/contained in the electric field and 50% in the magnetic field. Again, general statements from specified cases."

They are not quite the same.

I am not quite sure about the concept of energy at a point that you discuss, isn't it zero?

You falsely accused me of treating powers other than
as scalars. Now you are trying to twist my denial into
something untoward. Just how low are you willing to
stoop to discredit Hecht, Born & Wolf, and Dr. Best?

> Is there, or is there NOT a cosine term in the interference equation?

Yes, there is. Look in Born and Wolf and Hecht's "Optics".
There it is. I didn't put it there. The cosine term is
the angle between the two interfering voltages. All three
authorities, Hecht, Born, and Wolf, present the same
watts/unit-area equation with a term that they call the
interference term. Your argument is with them, not with me.
Watts/unit-area is certainly a scalar, yet all the experts
insert a cosine term into the scalar equation. That you don't
comprehend is somewhat ironic, wouldn't you say?

> I wonder if you'd care to comment on the other mathematical techniques

Please don't blame me. Hecht says in "Optics" that destructive
interference somewhere else allows the constructive interference
that we are experiencing. I didn't invent the concept. It was
invented by optical physicists before I was born. That you
are completely ignorant of the concept is downright appalling.
It just goes to show that people who believe they know everything
rarely know anything.

> I'm still trying to parse how neglecting units makes it ok to
> use equations as you see fit. $100 + $100 + 2*SQRT($100*$100) = $400
> (The third term represents the amount of money that isn't somewhere else
> and should therefore be mine.) ;-)

Here's equation (15) on page 259 of Born and Wolf's, "Principles
of Optics". Intensity is certainly a scalar value in watts/unit-area.

Why do you think Born and Wolf would put a cosine function into a scalar equation? Up until you discovered them doing such a dastardly thing, they were your heroes.

Imax = I1 + I2 + 2*SQRT(I1*I2)*cos(A) (15)

Does watts/unit-area have a phase angle? No. But there is a phase angle associated with the corresponding two E-fields.

As far as I know, a money equation doesn't possess an interference term but intensity equations, irradiance equations, and Poynting vector equations do indeed possess an inteference term. Here's what Hecht says in "Optics". " Briefly then, optical interference corresponds to the interaction of two or more lightwaves yielding a resultant irradiance that DEVIATES FROM THE SUM OF THE COMPONENT IRRADIANCES." You are objecting to the deviation from the sum of the component power densities. Please take that up with Hecht.

Maybe the head of your department could explain the interference term in the irradiance-intensity-Poynting vector equation to you. But if I were you, I wouldn't expose your gross ignorance to him.

All anyone reading this posting has to do to see just how confused Jim really is, is to read a copy of "Optics" by Hecht, or a copy of "Principles of Optics", by Born and Wolf.

> exact nature of the "redistribution" if NOT reflection from a partially
> reflective surface?

It is impossible for a "partially reflective surface"
to reflect 100% of the intensity. My two step process
explains 100% reflection. Walt's virtual short explains
100% reflection. How do *you* explain 100% reflection
from a partially reflective surface? Time to cease the
mealy-mouthing and hand-waving and give us some facts.

A B
i=1.0 | i=5.83 | i=1.0
100w laser---air---|--1/2WL thin-film--|---air---...
<--Pref1=0w | <--Pref2=100w | <--Pref3=0w
Pfor1=100w | Pfor2=200w--> | Pfor3=100w-->

The intensity reflection coefficient seen by the internal
reflected wave is 0.5 yet the net reflection is 100%. I
have explained how that is possible through wave cancellation.
You have not explained how that is possible without wave
cancellation. Time to put up or shut up.

[Example snipped]

Cecil,

This is a rather curious notion. Where did you get the idea that waves must be perfectly aligned to "cancel"?

Suppose I set up an experiment in which two coherent laser beams are misaligned by, say, one picoradian. The phases are adjusted so that the waves "cancel" in the region of overlap. This is much the same as the Java picture you like to reference from the FSU Magnet Lab. Any measurement that might be made in the overlap region would show the destructive interference, or "cancellation" if you wish. However, the beams are not perfectly aligned, so eventually the overlap ceases, and the individual beams proceed on toward infinity. I believe most people would agree that those exiting beams would not be altered by any interaction or interference that might have occurred in the lengthy overlap region. (That is a very easy experiment that can be conducted in any elementary optics lab.)

OK, so now we fine tune the illuminating mechanism so that the two beams are perfectly aligned. Are you saying that there is now some fundamental physical difference, and that the beams indeed cancel?

What is the equation that provides such a dramatic change resulting from an adjustment of one picoradian? What reference is there for this dramatic change mechanism?

Again, I post the Hecht and Born & Wolf equation for intensity-irradiance, which is certainly an equation involving scalar values. Please answer the question: Why do Hecht and Born & Wolf insert a cosine term into their scalar intensity-irradiance equations? If it is OK for them to do it, why is it not OK for me to do it?

Itot = I1 + I2 + 2*SQRT(I1*I2)*cos(A)

You seem to think the act of inserting a cosine term into a scalar equation is an abomination. Please explain that criticism of Hecht, Born & Wolf, and me. It's past time to put up or shut up.

Hi Walt,

I did not say that, or in my view, imply that, it is your own interpretation of what I did say. I did make comment limited to Chapter 3 of Reflections II, and I stand by that comment.

Chapter 3 does not discuss stub matching at all, though you may apply principles that you develop in Chapter 3 to your discussion / analysis in later chapters, including to stub matching.

Apologies - what I meant to say was that waves must be perfectly
aligned to totally cancel. When I say "wave cancellation", I
am usually talking about total wave cancellation, as occurs at
a perfect Z0-match. I will try not to make that same mistake
in the future.

Waves need not be perfectly aligned to partially cancel.
Waves must be perfectly aligned to totally cancel. Hope
that clears up the confusion about what I meant to say.

And of course, partial wave cancellation can extend from
almost none to almost total. However, total wave cancellation
obviously requires perfect alignment.

I have to agree with what Richard and some others have said.

First, that you've done a tremendous job of sharing your extensive knowledge and experience, and explaining transmission line phenomena in such a clear and understandable manner. We all owe you a great debt for this.

But second, that there's something which you do state that I and some others can't accept. And that is that a "virtual" short (or open) circuit causes reflections, or that waves reflect from it. I maintain that for either to happen requires that traveling waves interact with each other. The "virtual" short or open is only the result of the sum -- superposition -- of traveling waves. Those traveling waves, and hence their sum, cannot cause a reflection of other waves, or alter those other waves in any way. Only a physical change in the (assumed linear) propagating medium can alter the fields in a traveling wave and cause a reflection. A real short circuit is in this category; a virtual short circuit is not. It doesn't matter if the waves are coherent or not, or even what their waveshapes are or whether or not they're periodic -- as long as the medium is linear, the waves cannot interact.

You have clearly shown, and there is no doubt, that waves behave *just as though* a virtual short or open circuit were a real one, and this is certainly a valuable insight and very useful analysis tool, just like the "virtual ground" at the summing junction of an op amp. But I feel it's very important to separate analytical tools and concepts from physical reality. If we don't, we're led deeper and deeper into the virtual world. Sooner or later, we reach conclusions which are plainly wrong.

There are many other examples of useful alternative ways of looking at things, for example differential and common mode currents in place of the reality of two individual currents, or replacing the actual exponentially depth-decaying RF current in a conductor with an imaginary one which is uniform down to the skin depth and zero below. But we have to always keep in mind that these are merely mathematical tools and that they don't really correspond to the physical reality.

Unless I've incorrectly read what you've written, you're saying that you've proved that virtual shorts and opens reflect waves. But in every example you can present, it can be shown that all waves and reflections in the system can be explained solely by reflections from real impedance changes, and without considering or even noticing those points at which the waves superpose to become virtual short or open circuits. That, I believe, would disprove the conjecture that virtual shorts or opens cause reflections. Can you present any example which does require

virtual shorts or opens to explain the wave behavior in either a transient or steady state condition?

If I've misinterpreted what you've said, I share that misinterpretation with some of the others who have commented here. And if that's the case, I respectfully suggest that you review what you've written and see how it could be reworded to reduce the misunderstanding.

Once again, we all owe you a great deal of thanks for all you've done. And personally, I owe you thanks for many other things, including setting such an example of courtesy, civility and professionalism here in this group (as well in everything else you touch). It's one I strive for, but continually fall far short of.

I agree that this is the problem in Walt's otherwise brilliant work. Reflections are only caused by the direct interaction between electromagnetic waves and matter. It is nevertheless valid to say that systems behave as though virtual impedances cause reflections. Virtual reflection coefficients are a clever tool and methodology for systems analysis. But it must be remembered that the propagation of electromagnetic waves is effected only by certain physical properties of matter, as described eloquently by James C. Maxwell and others. Those fundamentals of wave behavior are not different in the steady state than at other times.

I completely agree. I think if we got past this one issue, the newsgroup might actually find itself devoted more to discussions of antennas.

Grrr...thought I had posted a followup but it seems to have not shown up. I'll try to capture the essence of it here...

I think the idea of a virtual short and a virtual open is fine. I use similar things all the time in my work with op amps, with AGC controlled levels, and even with ratiometric measurements. However, in all these cases, including the transmission line virtual short and open, it's important to understand that it IS only an approximation to the real thing. There are times when the approximation is fine, as in Walt's posted example. However, there are times when the approximation fails, and it's important to somehow be aware of those times. One way to do that is to simply use the tools that are available on modern computers to keep track of line loss, and then the times when the approximation isn't good become obvious. For example...

I want to receive signals on 4.00MHz, but there's a very strong station on 4.30MHz. Knowing a little about transmission lines and stubs, I think, "I can build a resonator from a half wave of line shorted at both ends, and tune it to 4MHz. Then I can tap my 50 ohm through line from the antenna to the receiver onto that resonator, and it won't affect the 4.00MHz signal since it looks like an open circuit. If I position the tap point so that at 4.300MHz it's half a wave away from the short at the end of the line, it will see a 4.300MHz virtual short there, and it will eliminate the strong signal that's giving me trouble."

So I figure out that the line, using solid polyethylene dielectric line, needs to be about 81 feet long, and the tap point will be 75.53 feet from one end, 5.67 feet from the other. 81 feet of line could get pretty big, so I'll use RG-174 line. I build the resonator--you can look at it as two shorted stubs--and try it out. It doesn't seem to work very well, and I measure it and discover to my horror that the attenuation at 4.3MHz is only about 12dB, and the attenuation at 4.00MHz is over 8dB. I've gained less than 4dB net on my problem.

Realizing now that the problem is that the stubs I assumed were lossless really do have some loss, I try larger coax. Well, I've smartened up a bit by now and I first do some calculations and find that with RG-58 (about 0.6dB/100ft at 4MHz), I can get 18.6dB loss at 4.300MHz and only 4.8dB loss at 4.000MHz. That's better, but still not wonderful by any stretch of the imagination.

With RG-8, at only about .19dB/100 feet loss at 4MHz, it improves to 28dB loss at 4.300MHz and only about 1.9dB at 4.00MHz. That wouldn't be bad, except that it's an awfully big pile of coax on the floor. At that point I go off and design a good LC filter to do the job, and find I can get less than a dB loss at 4.00MHz and fully 45dB loss at 4.300MHz, with modest size coils (smaller even than the coil of RG174, and much smaller than the RG8), and I can use a trimmer cap to fine-tune the notch to get the most benefit. (BTW--you can also use trimmer caps to tune stubs...which can save lots of cutting.)

You can develop a feel for when approximations like the virtual short and the virtual open actually work, but I think you need to go through several scenarios that show the good, but also the bad and the ugly, before you jump into blindly using an approximation. Given how easy it is for me to just include the loss of line in calculations, I'm unlikely to drop that in favor of the approximation. It's practically as easy for me to put loss into my calculations as it is to leave it off, and putting it in makes it immediately obvious when the approximations fail.

Cheers,
Tom

Good idea Tom. Roy: Besides RFSim99, Agilent's free AppCAD program has a mode where it can overlay a set of data on a Smith chart, having read it from the Touchstone ("standard network analyzer format") files.

Well, I dunno about that. Try this experiment:

Take a "poor" short, say 1 ohm, and transform it through a lossless
1/4 wavelength line of Zo=200 ohm. The result will be 40,000 ohm.
Now transform this 40K ohm load through another lossless 1/4
wavelength line of Zo=10 ohm. The result of this transformation will
be a "virtual" 0.003 ohm.

Is that an improvement? [g]

But that's wrong. If it was right, then a partially reflective surface couldn't be used to prevent reflections either.

Think about the transient period. You're right that after the first bounce only half the intensity, for example, is apparent. But using the physical reflection coefficient you can plot the intensity increase steadily as a function of time all the way up to steady state. That's because at every time t, the remainder of all previous reflections are superposed. Yes, interference describes macroscopically what happens - it's a short cut to steady state. But nothing about the reflective surface changes - before or after steady state. It is only your idea of 'energy in the wave' that needs to change a little.

Hi Wes,

There is always a rational example to deflate absolutisms. Thanx for
the interesting twist of transmission line.

However, I wouldn't want to be the wallet that pays for this.

While operating on 10M I have observed that a halfwave vertical dipole will communicate to different areas than a 1.25wl vertical monopole an example would be that during a band opening the 1/2 wl antenna may be working predominantly into New York while the 1.25 wl antenna is working best in California or was it vice versa. This has proven useful for me, instead of fighting a pile-up and can just talk somewhere else. The two verticals may soon be replaced with a tri-bander and I was wondering if I could get this same type of effect by tilting the antenna vertically(no change in polarity) with a remote controlled device. I think it would be pretty cool to hear different areas of the country pop in and out as the elevation of the antenna is changed.

From my experience of years ago, must say: most
likely makes makes little , or no difference!
Reason, is 1) depends WHERE you are , relative to
the satelite , and 2) the polarity of the
satelite , relative to your location , and most
likely NOT in the plane of your antenna, at
any given time. The antenna on a satelite is
more or less locked towards earth, with a
magnet, so far-so good, but at WHAT polarity?
This is the reason MOST great stations use
Circular Polarization. Max loss is 3 dB, for
polarity consideration, tho there would be a
loss, from the ANGLE of the pattern , from the
satelite (if I understand this correctly)
With linear polarization, there will be times
of deep fades, and also periods of great signal
strength. This dates me, and from A-06 and A-07
used 1/4 whips, bent against a metal ground
plane, about 30 degs, tip of antenna faceing NORTH
and worked considerable stuff. For the Eleptical
orbit sats, you may need gain , and circular
polarization to be heard, tho better stations can
be contacted (the "Umph" is on their end)!
In sum total, then if you use linear polarization
you must accept the fadeing, tho you can make
many contacts, and hear I.S.S. qso's but not as
a solid signal. Hope this helps. Jim NN7K

Thank you, Roy, I appreciate your comments, as always. However, I knew that you have always considered that
virtual opens and shorts cannot cause reflections, and I was hoping my discussion would have persuaded you
otherwise.

So I ask you this: What then causes the total re-reflection at the stub point if not a virtual short circuit?
The re-reflection is real, but there is no physical short circuit at the re-reflection point. The resultant of
the reflection coefficients of both the forward and reflected waves of voltage and current possess the exact
reflection coefficients, 0.5 at 180ï¿½ for voltage and 0.5 at 0ï¿½ for current, that are present when the short is
a physical short, except that the magnitude would be 1.0 instead of 0.5. The only operational difference is
that a physical short on the line prevents wave propagation in both directions, while the virtual short is
transparent in the forward direction, but opaque in the reverse direction.

So I repeat the question: If a virtual short circuit cannot cause reflections, then what causes the reflection
at the stub point?

Incidentally, there has been mention of 'virtual' reflection coefficients. I can't agree with this
terminology. Reflection coefficients are real, and for every reflection coefficient there is an equivalent
real impedance. As such, it is just as valid to use reflection coefficients in transmission-line analyses as
it is to use correspondingly-equal impedances.

How now, Roy?

Not only that, BUT IF you use copper pipe, you
may expect electrolysis , which will actually
eat the pipe, in 4 or 5 years, in soil. If you
go to your parts house (Lowes, or Home Depot), you
will notice unions which are INSULATED for copper
plumbing . I had a water line replaced with copper
the plumber said with those unions, can get 25-30
years out of your new pipe, without, more like
5 years before holes appear! It ain't cheap
replaceing couple hundred feet of water supply
pipe! This also affects steel piping, tho not
so rapidly!

Hi Owen,

I'm afraid we both got off the the wrong foot along the way. I'm sorry if I misinterpreted what you said in
the post where we got off track.

Quite possibly the misinterpretation arose in your referencing Chapter 3. When I saw that I assumed you had
made a typo, either for 4 or 23, both of which contain the stub discussions. And I thought I had earlier
referenced Chapter 4. I didn't realize you had actually reviewed Chapter 3 instead of 4.

Perhaps also you missed my two responses to your post of 4-7-07 in the earlier thread, in which I accepted
your apology (not needed). Anyway, the issue where I felt you were wrong is my interpretation that you
believed my statements concerning use of reflection coefficients was wrong because they are applicable for use
in analysis only when the transmission lines are either lossless distortionless.

I hope we can resume on a new footing.

Sincerely,

Walt

Walt, the last thing I want to do is to upset you.

You have a considerable investment in your publications, and they are a great service to the amateur community, and a credit to you.

Much of the discussion isn't so much about what happens in the transmission line, it is about simplified explanations, explanations that are appealling to learners, and the extension of those simplified explanations to the more general case. If you look back over the threads, you and I have both intiated threads where "explanation" was a key word in the subject line.

My own view is that whilst analysing a simple case that can be seen as special cases is a good way of introducing the issue that is to be dealt with (eg showing the inconsistency of the Vf/If=Zo constraint in the initial wave that travels along a transmission line, and the V/I ratio a s/c or o/c load), one needs to move on to dealing with the more general load case, even if in a simplified context (eg lossless line). The "rules" that are derived have to be clearly qualified with the applicable limits.

To overemphasis the simple / easy cases and downplay the error of approximation is at risk of consigning all problem solving to simplification to a trivial case and applying the solution of that trivial case to the real problem without appreciation of the leap that might entail.

Whilst it is no doubt appealing to some to see a virtual s/c or virtual o/c as an explanation for the single stub tuner example, and it might be a suitable model for that purpose, it gives the learner a new analysis tool (without limitations), the virtual s/c or o/c. How perfect does a virtual s/c need to be to be approximately effective? If I have an approximately lossless feedline with a VSWR of 100:1, will the virtual s/c at a current maximum prevent energy propagating in the same way as the virtual s/c in the stub explanation, or could each virtual circuit choke of x% of the energy flow? Can you solve a two stub tuner using only virtual s/c or o/c?

It is a challenge to devise simplified explanations that don't contain errors that need to be un-learned to develop further. I hate to say to a learner "throw away what you already know about this, because the explanation you have learned, understood, and trusted is wrong in part, and we need to discard it before we move on to a better understanding... trust me...".

Owen

That's faulty logic born out of ignorance.
Assume s11 = 0.707 in the S-Parameter reflected
voltage equation. a1 is the normalized forward
voltage from the source. Let's assume a1 = 10.

b1 = s11(a1) + s12(a2)

the initial transient state reflection is

b1 = s11(a1) = 0.707(10) = 7.07 normalized volts

and *that term remains constant* throughout the transient
state and throughout steady-state. The impedance discontinuity
with s11=0.707 reflects 70.7% of the incident voltage, period,
no more and no less. The magnitude of a1 reflected by that
impedance discontinuity *DOES NOT CHANGE* from the very
first incidence of a1. So your statement above is obviously
false. Physical impedance discontinuities do not change their
reflection coefficients based on your whim.

So how does b1 wind up at zero? Not by changing s11(a1) as
you imply. b1 is eventually canceled by the buildup to steady-
state of s12(a2) from zero to a magnitude equal to s11(a1) and
a phase opposite of s11(a1). That's *wave cancellation* in action.
What happens to the energy in the canceled waves?

So your premise is completely flawed. s11(a1) doesn't change.
s12 doesn't change. s21 doesn't change. s22 doesn't change.
What changes is the s12(a2) term which is the reflections
from the load. b1 decreases increment by increment due to
the wave cancellation between the fixed value of s11(a1)
and the ever increasing value of s12(a2) until steady-state
is reached and b1 has become zero. At steady-state, s11(a1)
is still equal to 7.07 normalized volts. It has not changed.
Contrary to your assertion, it will not change as long as
a1 is applied.

s11(a1) = 7.07 unchanging throughout the initial transient
build-up and through steady-state. Anything else would
require magic.

b1 is initially equal to 7.07 because a2 is zero.

s12(a2) will eventually build up from 0 to 7.07 at which
point the *net reflections are eliminated by wave cancellation*.

As b1 is decreasing to zero at steady-state, b2 is increasing
to its steady-state value in the other direction. b1 is
undergoing increasing destructive interference and b2 is
undergoing increasing constructive interference until the
time when b1 = 0 and therefore |b1|^2 = 0, i.e. net reflections
are eliminated.

Richard Clark, KB7QHC wrote:
"A poor physical open or physical short will never be improved by ANY transmission line mechanics."

An open-circuit 1/4-wave stub is an open circuit at both ends, physically. As such, its input is a poor short-circuit until it receives a reflection from its far end. After the reflection reaches the stub`s input, it becomes a virtual short-circuit. This occurs at its "poor physical short" input.

This is a dramatic improvement by transmission line mechanics when this is the desired effect.

Best regards, Richard Harrison, KB5WZI

Let's look at a 1/4WL open stub.

```
source ----------------------------------+
|
| 1/4WL
|
|
open
```

The transmission line and stub are the same Z0 and
both are lossless.

The virtual impedance at point '+' is zero but there
is no physical impedance discontinuity at point '+'.
Are there any reflections originating at point '+'?

If we straighten out the line,

```
1/4WL
source-----------------------------------+-----------open
```

Are there any reflections originating at point '+'?

HAs anyone ever tried using a long whip with a screwdriver matching
network. For example I have a telescoping 18ft whip and I was
wondering how it might work with it. I have never used a screwdriver
antenna before and the whip collapses to a little over 6ft.

It's done quite often for non-mobile antennas,
fixed and portable. Mobile antennas are limited
to about 12.5 ft above the ground.

I'd think that this diode-like property of virtual shorts would be a major clue that they're not real, but a mathematical convenience. The virtual short is a point where the sum of the voltages of all waves, forward and reflected, add to zero. If this condition causes waves to reflect when struck from one direction, what possible physical explanation could there be for it to do absolutely nothing to waves traveling the other way?

> So I repeat the question: If a virtual short circuit cannot cause reflections, then what causes the reflection
> at the stub point?

My answer is this: There is no total re-reflection at the stub point. It only looks that way.

As you've observed, the waves (traveling in one direction, anyway) behave just as though there was such a re-reflection. But the waves actually are reflecting partially or totally from the end of the stub and other more distant points of impedance discontinuity, not from a "virtual short". The sum of the forward wave and those reflections add up to zero at the stub point to create the "virtual short", and to create waves which look just like they're totally reflecting from the stub point. This has some parallels to a "virtual ground" at an op amp

input. From the outside world, the point looks just like ground. But it isn't really. The current you put into that junction isn't going to ground, but back around to the op amp output. Turn off the op amp and the "virtual ground" disappears. Likewise, waves arriving at the virtual short look just like they're reflecting from it. But they aren't. They're going right on by -- from either direction --, not having any idea that there's a "virtual short" there -- that is, not having any idea what the values or sum of other waves are at that point. They go right on by, reflect from more distant discontinuities, and the sum of those reflections arrives at the virtual short with the same phase and amplitude the wave would have if it had actually reflected from the virtual short. Like with the op amp, you can "turn off" the virtual short by altering those distant reflection points such as the stub end.

Please let me emphasize again that not I or anyone else who has posted is disputing the validity of your matching methods or the utility of the "virtual short" concept. The only disagreement is in the contention that the "virtual short" actually *effects* reflections rather than being solely a consequence of them.

> Incidentally, there has been mention of 'virtual' reflection coefficients. I can't agree with this
> terminology. Reflection coefficients are real, and for every reflection coefficient there is an equivalent
> real impedance. As such, it is just as valid to use reflection coefficients in transmission-line analyses as
> it is to use correspondingly-equal impedances.

I don't use "virtual reflection coefficient" by name or in concept, although it might have some utility in the same vein as "virtual short". However, great care would have to be used, as it must with virtual shorts, to separate analytical conveniences from reality. But I'll leave that discussion to others, and don't want it to divert us from the important point at hand.

> How now, Roy?

A question: Do you think you can present an example where a "virtual short" is necessary to explain the impedances, voltages, and currents -- or any other measurable properties -- on a transmission line? Where a person who assumes that *no* reflection takes place at "virtual shorts" but only at physical discontinuities would be unable to arrive at the correct result? If reflections really do occur at "virtual shorts", I would think that this phenomenon would have a profound effect on transmission line operation, to the extent that a valid solution couldn't be obtained if it were totally ignored. I maintain that such an example can't be found, because in fact reflection takes place only at physical discontinuities and not at "virtual shorts". Waves in a linear medium simply don't reflect from or otherwise affect each other. I'm not saying that you can't apply the analytical concept of "virtual shorts" to arrive at the same, valid, result. Or that the "virtual short" approach won't be easier. But I am saying that it's not necessary in

order to fully analyze any transmission line problem, simply because it's not real. Can you come up with such an example?

Roy

Hi Richard,

This kind of drama is found only on the stage.

A poor open is a poor short in reflection. Ever try tuning one that didn't wander the landscape? Burning money to achieve a working solution does not render it a dramatic improvement when other methods (like simply building a good shorted halfwave) are better.

Give me a reason why you suffered to build an open quarterwave, and it will embrace the issues of quality I already covered.

Owen Duffy wrote:
"I am not quite sure about the concept of energy at a point that you discuss, isn`t it zero."

Not when radio waves are passing by. These waves were likely produced by electrical energy in a wire somewhere that spread into space around the wire. Radio waves alternate around a zero value. If symmetrical about an axis, the waveforms may have zero average values. But that is not how we value the intensity of a rafio wave. We give it an rms or effective value which is 0.707 times its maximum voltage profuced during the cycle.

When speaking of power in an alternating energy value, it is not correct to say rms power. The effective a-c power value is its average.

I`m not a teacher, never have been, and never intend to be. I think I got into this discussion by declaring that 50% of the power in a wave resided in each of its two constituents.

I shall argue no more nor try to explain any more on the topic of radio waves in this thread. Fred Terman is the master of all masters in my books and I suggest beginning on page one of his 1955 version of "Electronic and Radio Engineering" to learn all about "Radio Waves".

From page 1:
"One-half of the electrical energy contained in the wave exists in the form of electrostatic energy, while the remaining half is in the form of magnetic energy."

The key word there is "utility" - the virtual short/open concept is *useful* as a short-cut in our thinking. But concepts are only useful if they help us to think more clearly about physical reality; and short-cuts are dangerous if they don't reliably bring us back onto the main track.

We know that in reality both the forward and the reflected waves take a side-trip off the main line into the stub, and from the far end of the stub they are reflected back to rejoin the main line at the junction. Since an open- or short-circuited stub has a predictable effect at the junction where it is connected, then we could save a little time by noting that a stub is present, and simply assuming what its effect will be.

Within those limitations, I don't have any particular problem about calling the effect a "virtual short" or "virtual open". As Richard said, it is only a metaphor. We are using the word "virtual" as a label to remind ourselves that the effect at the junction is not the same as a genuine physical short or open circuit on the main line.

Where the concept goes off track is if anyone forgets about the limitations, and begins to believe that a metaphor has physical properties of its own. (It doesn't, of course - all of the physical effects on the main line are caused by the stub, and the stub is the only place where the root causes can be found.)

If there is any problem in using a short-cut, then simply forget it - step back and analyse the complete physical system including the stub.

Agreed. It all comes back to "usefulness" or "utility" again. As I said, concepts are only useful if they help us to think more clearly about physical reality - and "virtual reflection coefficient" has exactly the opposite effect.

Also, please note that in an S-Parameter analysis, all
reflection coefficients are physical, not virtual.
Since I may have used the term first here, let me
explain what I meant by it. a1, b1, a2, and b2 are
the S-Parameter normalized voltages. Below, a1=10,
b1=0, b2=14.14, and a2=10. s11 is the physical reflection
coefficient encountered by forward wave a1. s11 is
(291.4-50)/(291.4+50) = 0.707. In an S-Parameter,
the reflection coefficient is NOT the ratio of b1/a1.

a1--> b2-->
<--b1 <--a2
100w---50 ohm line---+---1/2WL 291.4 ohm line---50 ohm load
Vfor1=100V--> Vfor2=241.4V-->
<--Vref1=0V <--Vref2=170.7V

Given the actual voltages, someone might say the reflection
coefficient is Vref1/Vfor1 = 0. That is a virtual reflection
coefficient. The physical reflection coefficient at point '+'
remains at 0.707. Vfor1 sees a virtual impedance of 50 ohms
at point '+' during steady-state because of the wave cancellation
that results in a net Vref1=0. But the physical reflection
coefficient doesn't change from power-up through steady-state.
One has to be careful to specify whether the physical rho,
(Z02-Z01)/(Z02+Z01), is being used or whether the virtual
rho, Vref1/Vfor1, is being used. One advantage of an S-
Parameter analysis is that virtual reflection coefficients
are not used and all reflection coefficients are physical.

Source record: 42943

Thanks for the input. I suspected as much, but wanted to hear what others thought. I have a few dozen contacts on VO-52 with the vertical Diamond X-50, so it has given me decent results. I also know that my chances of using the more distant satellites are pretty nil, but I'm OK with that. I don't plan on being big into satellite communications, just looking for something maybe a little better then the X-50. Matter of fact, the X-50 may be better than the loop because it does a have a little gain associated with it. And, yes, I am aware of the rapid fading due to satellite rotation and changes in polarity. On the other hand, the loop would offer me an antenna that will work better on 144/440 SSB/CW. So, the dual band loop does offer me a use other than satellite work.

Thanks to all who gave advice!

Assuming you're looking for theory...
Look for articles by David Pozar or search for "microstrip patch
antenna"

or, most antenna textbooks have a section describing them.

A quick and dirty model is to consider them as two small magnetic
loops.

Search the agilent website for the original application note on S-parameters.. it provides a great explanation of why S-parameters are used.

You've correctly assessed the situation.. at microwave frequencies, it's much easier to measure forward and reflected signals (and calibrate for non-ideal directional couplers, etc.) than to measure voltage and/or current.

Hi Mario,

If you have limited time, hire an antenna specialist to help you
setting up the seminar an providing knowledge.

If you have more time, Artech House has some nice books on strip line
and patch antennas (www.artechhouse.com). Go to the antennas &
propagation section or us the search option.

If you are just interested In parameters (bandwidth, radiation
pattern, axial ratio, gain, etc) from existing antennas, try to find
antenna manufacturers and look into their datasheets.

Best Regards,

Wim
PA3DJS

Roy Lewallen, W7EL wrote:
"Those traveling waves, and hence their sum, cannot cause a reflection of other waves, or alter those waves in any way."

Let`s reason together on the situation in a quarter-wavelength short-circuited transmission line stub. I maintain it has a hard short on its far end and a high impedance on its near end.

A high impedance means just what it says. You can put a high voltage on it and the resulting current is small.

Reflection from a short-circuit results in a 180-degree voltage phase reversal at the short.

A round-trip on a 1/4-wave stub produces an additional 180-degree phase reversal.

This means thats volts returning to the open-circuit end of the stub are about of the same phase and magnitude as when they started out.

Nearly identical voltages appear at the same pair of terminals from opposite directions. Significant current flows in either direction? I think it does not.

Where voltage causes insignificant current flow, we have a high impedance.

That is why King, Mimno, and Wing on page 30 of Transmission Lines, Antennas and Wave Guides say:
"Since the input impedance of a short-circuited quarter-wavelength section of transmission line is a very high resistance, short-circuited stubs may be used to support the line."

Partially reflective surfaces can (and are) in fact used to prevent
reflections, just as they are used to 100% re-reflect partial
reflections from a load.

> The magnitude of a1 reflected by that

That was the main point of my post, Cecil. The reflective coefficient
DOES NOT CHANGE. You're the one who claims that it does.

> What happens to the energy in the canceled waves?

There is no energy "in" cancelled waves. Your ideas in that regard are
faulty. Energy only exists where fields aren't cancelled. That
should be obvious even to someone with propensities such as yours.

Hi Richard,

One example begs another, symmetrical one; and here is the example of my asking you why you would struggle through building an open line reflected as a short (the quarterwave section).

For argument's sake, let's amend KM&W to say:
"Since the input impedance of a open-circuited quarter-wavelength section of transmission line is a very low resistance, open-circuited stubs connected in series with the line elements may be used to support the line."

This statement is equivalent in the transmission line mechanic's tool kit, certainly. However, it brings with it the difficulties of maintaining a "good" open (especially when that open is in close proximity to earth, or at least to the press of humanity). Casting those problems into the line obviously presents loss issues of a poor virtual short.

This conforms to my experience with many plumbing designs on the microwave bench. The absence of open quarterwave sections was nearly universal due to the problems of their implementation. It takes little effort to realize why KM&W did not offer this alternative. If you browse Terman, he also avoids such constructions.

Hi Jim,

How has this inversion arrived? Cecileo offering emphatic testimony to the Cardinals "It certainly doesn't move!" and no energy "in" cancelled waves?

Both waves exist as the absence of either would easily reveal. There may be no power to extract due to their offsetting contributions, but that doesn't prove they have vanished (which, in the context of sight, interference, and light diminishing in regions necessarily demands a load to demonstrate).

The language of photon shuffling and energy re-distribution lends the logic of divine intervention to scientific theory. These verbs are active and require an actor. If we were to travel down that path, the patterns of intelligent design interference would be explained in epicycles and crystalline spheres of angels' guiding results.

>
> Yuri, K3BU.us

High Yuri,

I try again.

Ratiation pattern
As NVIS radiation comes from near 90 degrees elevation, the antenna receiving the incoming wave will operate at near maximum gain, no matter the orientation (in horizontal plane) of the dipole. The gain of a dipole under 75 degrees is less then 1 dB below the maximum.

To orient your antenna to get a nul, you have to use a vertical dipole (or vertical monopole). So radiation pattern is not of importance.

Polarization,
If the ionosphere would act as a pure mirror reflector, and there was no free charge, you are right, orientation of both antennas would matter. As you do not know the amount of polarization change, you cannot predict the optimum orientation.

Prove it yourself by using a hand held antenna (for example small vertical loop, or horizontal small dipole). Listen to an NVIS station (at about 50..100 mile from you) and rotate the antenna around the Z as. You should do this fast enough to distinguish between fading. You will find certain orientations with less reception, but the orientation (with minimum reception) will vary (that can be within a minute because of the change in overall faraday rotation). You will seldom find a real nul. This is because of the existence of a more or less circular component.

If you want to be sure and also want to cover situations in which the refracted wave is almost linear polarized, you may consider two

(small) antennas (perpendicular to each other) and switch between the two.

During last year JOTA I had plenty of space to use two half wave dipoles, but it wasn't worth to do. I checked it with a simple hand held vertical tuned loop antenna by rotating the antenna round the Z-axis.

Best regards,

Wim

...

Indeed. I was thinking about this in terms of short-cuts before reading Ian's post. What if you take a short-cut and it just takes you off into the woods? I'm not sure my posting about this made it into the thread in an intelligible way. (I fear Google may have sent it off on a "short-cut.")

The gist of it was that, although there are examples where considering points an even number of half-waves from a short as being shorts themselves work fine, there are plenty of counter examples too. I fear that people new to the use of stubs will be lulled into a false sense of security using that concept, when indeed it fails miserably at times. Especially in this age of computers and readily available programs to deal with lines, INCLUDING their loss, why would I use a concept that may take me on a short-cut that turns out to be the long way around?

What IS useful to me about the concept is NOT the calculation of the performance of a particular network of stubs, but rather in coming up with the trial design to test with full calculations. My example was the use of two stubs to give me a null on one frequency and pass another frequency; I can get a null by putting a "virtual short" at that frequency, and that's a line that's a half wave long on that frequency, shorted at the other end. But on a slightly lower frequency, it looks capacitive, so I can put another stub that's inductive in parallel with it to create an open circuit at the frequency I want to let pass. THEN I pull out the calculations with line attenuation included, and discover that in some situations it works fine, and in others, the performance is terrible.

It's a useful visualization tool and design aid; it's a poor analysis tool at best. At worst, it will lull you into building something that just won't work, wasting time and resources.

Cheers,
Tom

I'm not sure I understand the point you're trying to make. Nothing I've said disputes in any way that the input impedance of a shorted quarter wave stub is high. I'm quite able to make transmission line calculations and arrive at correct results.

You're certainly correct that there's very little net current at the open end of the stub. Yet there are waves traveling in both directions right through that point. Don't believe it? Then check the current anywhere else along the stub. How did it get there without going through the "open" at the input end?

Good. Then, Richard Clark must also be familiar with the grooved circular flange used in conjunction with a smooth flange to join waveguide segments. This groove isn`t just used to hold a neoprene gasket. It is also used as an electrical choke to keep the microwaves within the pipe. It is approximately a 1/4-wave choke and its high impedance across its open-circuit helps foil the wave escape. If virtual open-circuits didn`t work, the "choke-flange wouldn`t work either.

Hi Richard,

I have to admit that I do have difficulty arguing with nonsense, and
you've caught me at it. I've tried explaining this to Cecil in the
context of energy transfer, but without success. So I'm happy to
leave it to you to explain to Cecil how waves cancel but without
anhiliating the energy "in" them.

> And my point is that your opinion does not jibe with the National Electric
> Code.
> --
> Tom Horne

Please Tom, tell me in what way that the grounding system should be
sufficent on its own and not having to rely on the plumbing to provide
grounding for an electrical system in violation of the NEC. Also please tell
me how you intend to prevent the scenario I discribed where the ground
system was completely disconnected from the home when the well's metal
plumbing was replaced with plastic.

The Code is the min and max that an inspector can apply to an inspection This means that the inspector cant find fault with using plumbing for grounding if this is what the code says, it doesnt mean that the inspector can find fault if it is built better than code requirements, so again I say the code is written to a minimum spec. Your own definition of min max confirms this. Traditionally the NEC has the lowest minimum standard and the state and local codes usually have a higher standard., there may be some exceptions to this. I will will stipulate that using plumbing for ground may be "to code" in some places but it still is not a good way to ground your house and definately should not be used for a lightning ground.

>Roy
Hi R oy,

Consider my two explanations, or definitions of what I consider a virtual short--perhaps it should have a
different name, because of course 'virtual' implies non-existence. The short circuit evident at the input of
the two line examples I presented---do you agree that short circuits appear at the input of the two lines? If
so, what would you call them?

Roy, I'd like for you to take another, but perhaps closer look at the summarizing of the reflection
coefficients below. I originally typed in the wrong value for the magnitude of the resultant coefficients.
With the corrected magnitudes in place, the two paragraphs following the summarization now make more sense,
because the short circuit established at the stub point leads correctly to the wave action that occurs there.

Summarizing reflection coefficient values at stub point with stub in place:
Line coefficients: voltage 0.5 at +120ï¿½, current -60ï¿½ (y = 1 + j1.1547)
Stub coefficients: voltage 0.5 at -120ï¿½, current +60ï¿½ (y = 1 - j1.1547)
Resultant coefficients: voltage 0.5 at 180ï¿½, current 0.5 at 0ï¿½ WRONG
Resultant coefficients: voltage 1.0 at 180ï¿½, current 1.0 at 0ï¿½ CORRECT

Repeating from my original post for emphasis:
These two resultant reflection coefficients resulting from the interference between the load-reflected wave at
the stub point and the reflected wave produced by the stub define a virtual short circuit established at the

stub point.

The following paragraph shows how the phases of the reflected waves become in phase with the source waves so
that the reflected waves add directly to the source waves, establishing the forward power, which we know
exceed the source power when the reflected power is re-reflected. The same concept applies to antena tuners.

Again repeating for emphasis:
Let's now consider what occurs when a wave encounters a short circuit. We know that the voltage wave
encounters a phase change of 180ï¿½, while the current wave encounters zero change in phase. Note that the
resultant voltage is at 180ï¿½, so the voltage phase changes to 0ï¿½ on reflection at the short circuit, and is
now in phase with the source voltage wave. In addition, the resultant current is already at 0ï¿½, and because
the current phase does not change on reflection at the short circuit, it remains at 0ï¿½ and in phase with
source current wave. Consequently, the reflected waves add in phase with the source waves, thus increasing the
forward power in the line section between the stub and the load.

Keep in mind that the short at the stub point is a one-way short, diode like, as you say, because in the
forward direction the voltage reflection coefficient rho is 0.0 at 0ï¿½, while in the reverse direction, rho at
the stub point is 1.0 at 180ï¿½, which is why it's a one-way short.

You say that no total re-reflection occurs at the stub point. However, with a perfect match the power rearward
of the stub is zero, and all the source power goes to the load in the forward direction. Is that not total
reflection? Using the numbers of my bench experiment, assuming a source power of 1 watt, and with the
magnitude rho of 0.04, power going rearward of the stub is 0.0016 w, while the power absorbed by the load is
0.9984 w, the sum of which is 1 w. The SWR seen by the source is 1.083:1, and the return loss in this
experiment is 27.96 dB, while the power lost to the load is 0.0070 dB. From a ham's practical viewpoint the
reflected power is totally re-reflected.

In my example using the 49ï¿½ stub the capacitive reactance it established at its input is Xc = -57.52 ohms.
Thus its inductive susceptance B = 0.0174 mhos, which cancels the capacitive line susceptance B = -0.0174 mhos
appearing at the stub point.

My point is that the 49ï¿½ stub can be replaced with a lumped capacitance Xc = -57.52 ohms directly on the line

with the same results as with the stub--with the same reflection coefficients. In this case one cannot say
that the re-reflection results from the physical open circuit terminating the stub line.

Various posters have termed my approach as a 'short cut'. I disagree. I prefer to consider it as the wave
analysis to the stub-matching procedure, in contrast to the traditional method of simply saying that the stub
reactance cancels the line reactance at the point on the line where the line resistance R = Zo. In my mind the
wave analysis presents a more detailed view of what's actually happening to the pertinent waves while the
impedance match is being established.

Walt,

Though admittance or impedance at a point on the mismatched line are
calculated from the underlying Zo and the reflection coefficient
corrected for line loss, they are easier to work in than the raw
reflection coefficient.

It is easier to explain why the stub is located at a position where Yn'=1
+jB than where Gamma=0.5<120 (assuming lossless line). It is relatively
obvious that where Yn'=1+jB, a shunt reactance of -jB from a s/c or o/c
stub will leave Yn=1 which is the matched condition.

Re your worked solution (above), I agree that the normalised admittance
looking into 30deg of line with load 16.667+j0 is about 1-j1.1547 (not
the different sign).

I make the normalised admittance looking into the stub about 0+j1.15 (and
the reflection coefficient about 0.5<-98, how do you get 1+j1.15?

The addition of the two normalised admittances 1-j1.15 + 0+j1.15 gives 1
+j0 which is the matched condition.

The design is correct, the stub results in a match at the stub connection
point (irrespective of what is connected on the source side of the
point), but I can't understand your maths above (allowing for the sign
error that I think you have made).

Is the reflection coefficient explanation a clearer explanation than
using admittances?

Owen

BTW, my line loss calculator solutions (http://www.vk1od.net/tl/tllc.php)

Walt, before digging into your recent posting, I'd really like to get one issue settled. I think it would be helpful in our discussion. The issue is:

Can you find even one example of any transmission line problem which cannot be solved, or a complete analysis done, without making the assumption that waves reflect from a "virtual short" or "virtual open"? That is, any example where such an assumption is necessary in order to find the currents, voltages, and impedances, and the magnitude and phase of forward and reverse voltage and current waves?

Depends on the instrumentation available for obtaining the raw data.

Yes Owen, you're right. I added the y values at the last moment, and didn't catch the errors. Both the line
and stub signs are reversed. Sorry 'bout that.

>I make the normalised admittance looking into the stub about 0+j1.15 (and
>the reflection coefficient about 0.5<-98, how do you get 1+j1.15?

Normalized y looking into the stub directly is y = 0 + 1.1547, but looking at the stub while on the line at
the 30ï¿½ point is y = 1 + 1.1547. To view the stub separately on the line the line is terminated in 50 ohms,
because the real component of the line impedance at the match point is 50 ohms.

>The addition of the two normalised admittances 1-j1.15 + 0+j1.15 gives 1
>+j0 which is the matched condition.

Of course.

>The design is correct, the stub results in a match at the stub connection

The resultant coefficients are obtained by simply adding the voltage coefficients and the current
coefficients, as in the adding of the line and stub admittances.

>Is the reflection coefficient explanation a clearer explanation than
>using admittances?

Not at all, Owen, but as I said in the original post, the instrument I acquired early in my time with the RCA
antenna lab was the PRD-219 reflectometer. At that time I considered it the best instrument for measuring
transmission line circuitry at VHF, and because it delivered readings in reflection coefficient I became
somewhat more efficient in my thinking process using that mode.

No Roy, of course not. I am not attempting to assert that reflection coefficients should be used in such an
analysis. I'm only asserting that it's another way of performing an analysis, one that I believe paints a more
visible picture of the how the pertinent waves behave in the circuit.

If I still haven't persuaded you that it's a viable way of analyzing the impedance matching function then I'll
back off and not pursue the issue any further.

Incidentally, you didn't answer my questions.

You have a junction where three current paths appear in parallel, we can
add the admittances of each of those paths.

We are agreed that admittance of the load+30deg line is 1-j1.15, and that
of the stub is 0+j1.15, so the only place the additional 1+j0 can come
from is the source+line branch.

If that is the case, then your explanation of the stub (which I assume to
be a steady state explanation because you are talking about frequency
domain admittances), depends on the source admittance (or impedance). If
the equivalent source impedance at the junction figures in the calcs, you
are saying that the VSWR on the line from source to junction depends on
the source impedance... I thought we got over that error.

My view is that the stub in shunt with the 30deg line+load results in an
equivalent impedance of approximately 50+j0 at the junction, irrespective
of what is on the source side of the junction.

We're certainly not communicating well! I have never questioned that the use of "virtual shorts" is another way of performing an analysis, nor that it helps visualize some of the things going on.

> If I still haven't persuaded you that it's a viable way of analyzing the impedance matching function then I'll
> back off and not pursue the issue any further.

Nor have I questioned that it's a viable way of analyzing the impedance matching function.

If you'll read what I've written, you'll hopefully see that my only point of contention is with your claim that waves reflect from a "virtual short". They do not. And the lack of a single example of a system whose analysis requires this to happen is evidence that they do not.

If you back off and not pursue the issue any further, you'll continue with your belief that "virtual shorts" cause reflections. And I'm afraid that will detract from the wealth of accurate and useful things you do say. So please continue. But don't waste time arguing that the concept of "virtual shorts" is a useful analytical tool. I've always agreed with that, and haven't seen any postings indicating anyone else doesn't.

> Incidentally, you didn't answer my questions.

I wanted to get an answer to mine, first. Now that I have, I'll answer yours.

I'd call them "virtual shorts". If they were short circuits, we should be able to connect a wire across the transmission line at that point with no change in transmission line operation. But we can't. While things will look the same on the generator side, they won't be the same beyond the real short. So they aren't short circuits.

There's no need to repeat this. I'm well acquainted with transmission line phenomena, and understand fully what's happening. I have no disagreement with this analysis. I would draw attention to the fact that the "virtual short" is, as you say, simply the superposition (interference) of traveling waves. So there is nothing at that point except the traveling waves which pass through that point.

> The following paragraph shows how the phases of the reflected waves become in phase with the source waves so
> that the reflected waves add directly to the source waves, establishing the forward power, which we know

Sorry, I'm not going to divert onto the topic of propagating power, either instantaneous or average. If that concept is required in order to show that waves interact with each other, then it simply shows that the concept is invalid. Let's stick to voltages and currents. If that's not adequate, then I'll exit at this point, and turn the discussion over to Cecil. That's his domain, not mine.

> Again repeating for emphasis:

Ok so far. . .

thus increasing the
> forward power in the line section between the stub and the load.

Again, let's leave power out of it, ok?

> Keep in mind that the short at the stub point is a one-way short, diode like, as you say, because in the
> forward direction the voltage reflection coefficient rho is 0.0 at 0ï¿½, while in the reverse direction, rho at
> the stub point is 1.0 at 180ï¿½, which is why it's a one-way short.

The voltages, currents, waves, and impedances impedances on the line are just the same as if there were a diode-short at that point. Which is why it's a useful analytical tool. But all there really is at that point are some interfering waves, traveling through that point unhindered.

> You say that no total re-reflection occurs at the stub point. However, with a perfect match the power rearward
> of the stub is zero, and all the source power goes to the load in the forward direction. Is that not total
> reflection?

Not from the "virtual short" -- it only looks like it. The re-reflection
is actually occurring from the end of the stub and from the load, not
from the "virtual short". If, for example, you suddenly increased the
source voltage, there would be no reflection as that change propagated
through that "virtual short". (That is, after a delay equal to the
round-trip time to the "virtual short", you'd see no change.) The
apparent reflection from that point wouldn't appear until the change
propagated to the end of the stub and to the load (going right through
the "virtual short" unhindered), reflected from them, and arrived back
at the "virtual short" point. This is one of the ways you can tell that
a "virtual short" isn't a real short. Under steady state conditions, it
looks just like a real one. But it isn't. Waves which seem to be
reflecting from it are really reflecting from the end of the stub and
from the load -- they're passing right through the "virtual short", in
both directions.

Sorry, you're going to have to do this without propagating waves of
average power, or I'm outta here.

That's fine, I agree.

> In this case one cannot say
> that the re-reflection results from the physical open circuit terminating the stub line.

I most certainly can! And do. I don't see how your example furnishes any
proof or even evidence of wave interaction. I can come to the same
conclusion without any assumption of wave interaction, and you have
agreed (in your response to my question about finding an example that
requires interaction for analysis) that this can always be done.

I'm sorry, I disagree. It's a less detailed view, and it conceals what's really going on.

In my opinion, the potential harm can be much worse. If it causes you to buy into the notion that traveling waves interact in a linear medium, that opens the door to a whole universe of invalid conclusions. We've seen some of those promoted very vigorously in this newsgroup.

Richard, Thats not how it waste away. It is disovled from the inside by
galvanic action. If you couple copper to galvanized pipe you must use a
special coupler that electrically isolates the copper from the galvanized
pipe. This is usually a brass union with a neopreme, I think, insulator.

Hi Richard,

You got the dimensions wrong for the wrong reason. It is a halfwave shorted cavity (or transmission line sub-section). The cut channel is quarterwave, but the distance from the middle of the longest side of the waveguide is another quarterwave. The virtual short bridges the joined, but non-contacting faces of the two waveguide sections. There is no high Z action involved.

Further, there are two grooves, the outer one is for the neoprene gasket.

For others, when two sections of waveguide are joined, there is always the possibility that the two faces of the ends will not see a machined match (like an engine head to the engine block - which even there has problems of warp); hence the possibility of a break in continuity with an open circuit. Rather than burn money as a solution, engineers simply forced the problem by having the two faces separated and never in contact!

What they did to offset this deliberate open is they machined a circular groove around the flange of one section that was a quarterwave deep, and a quarterwave away from the voltage node for the waveguide's TE10 mode of transmission. The geometry of the groove and its distance from the node was very simple to control in comparison to guaranteeing fully flush mating faces (especially under the torsion of ship's movement, or simple heat expansion). This is a hallmark of engineering where the problem becomes the solution.

As always, a short is vastly more preferred than an open when casting back into the transmission line and the design engineers went to the

additional length to see it incorporated into the solution.

Dare I call the choke joint a virtual gasket?

Hi Jimmie,

Copper is higher on the Galvanic series than either Zinc or Iron.
(Zinc is lowest in the series aside from Magnesium)

While there is a possibility - though none that I know of - that for some
reason that copper may corrode before Zinc or its iron substrate, usually
the lower member of the series goes away first. Do you know what the
effect is?

I have heard of some low quality copper pipe that tends to spring
leaks after quite a few years. Perhaps this is what we are talking anout?

> reflections from a load.

Partially reflective surfaces cannot, by themselves,
reflect 100% of the incident energy. If it's partial,
it's not 100%, by definition. Any partially reflective
surface needs help from interference in order to
achieve 100% reflection. You know, that interference
that you deny exists.

> That was the main point of my post, Cecil. The reflective coefficient
> DOES NOT CHANGE. You're the one who claims that it does.

You continue to lie about what I said. I have said any
number of times that the physical reflection coefficient,
s11, is fixed and does NOT change. Why does someone who
is technically correct need to stoop to lying?

> There is no energy "in" cancelled waves.

The waves existed along with their energy components before
they were canceled. What happens to those energy components
after the waves are canceled. If one sets one phase equal
zero and the other phase equal 180 degrees, what happens to
the energy in the two waves at:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

There are two waves on the left existing with their respective
voltage and joules/sec. The result of total destructive interference
is zero voltage and zero joules/sec. What happened to the original
joule/sec components?

But that's just the point, Jim. You seem to believe the
pre-existing energy in those waves has been destroyed.
They obviously possessed energy before cancellation and
you say they possess zero energy after cancellation. If
that pre-existing energy is not destroyed, where did it go?

Here is how Hecht described interference in "Optics":
"... interference corresponds to the *interaction* of two or
more lightwaves yielding a resultant irradiance that deviates
from the sum of the component irradiances."

If traveling waves cannot interact in a linear medium, why
does Hecht say they do indeed interact?

To deny the body of laws of physics regarding EM waves from
the field of optics is an example of extreme ignorance.

I've seen this thread go back & forth. Back when my voice hadn't yet
changed, my folks bought a small piece of land for weekend travel-trailer
camping. At the time, there was power available but no water. We wanted AC

power for the otherwise self-contained trailer, and followed the requirements set down by the county PUD. We installed a utility pole, with service entrance, weatherproof breaker panel, and weatherproof outlet. All we had available for grounding was an 8' rod driven into the ground next to the pole. There was NO water pipe with which to connect the ground wire.

Fast forward to recent years (my voice has long-since changed, but now what graying hair I have left is falling out). When I decided to re-pour the concrete slab for my kitchen porch next to my service entrance, I found what was left of a 4' x 3/8" ground rod embedded in the old concrete (the entire #14 wire connected to it had also been embedded in the concrete.) There's no evidence of a connection to the water system. I replaced the rod with an 8" x 1/2" unit from the home improvement box store, and connected it to the service entrance with a #4 wire.

Thankfully, when the utility pole that serves my house continued to lean away from my house (and the neutral opened), the ground rod kept L1 & L2 from swinging too wildly. There's a transformer on the pole that serves my house, with a ground rod next to the pole. I guesstimated the ground resistance at about 1 or 2 ohms. Of course, when they repaired their drop wire, the PUD had to inspect my service entrance to make sure it met the minimum requirement. The entire pole & guying has since been changed. Still, I keep an eye on the slack in the drop wire to my house!

An interesting observation about ground rods... a 4'x3/8" rod = 56.55 sq. in surface area, while a 8'x1/2" rod = 150.80 sq. in surface area. Of course, more metal in the ground could only be better. Does anyone have a nice BIG copper kettle for sale? ;^)

Roy, seems you are the one with the invalid conclusions. Here
is a java-script of "traveling wave interaction in a linear medium".

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not
actually annihilated, ... All of the photon energy present in
these waves must somehow be recovered or redistributed in a
new direction, according to the law of energy conservation ...
Instead, upon meeting, the photons are redistributed to regions
that permit constructive interference, so the effect should be
considered as a redistribution of light waves and photon energy
rather than the spontaneous construction or destruction of light."

Does energy being redistributed in new directions really look
like a lack of interaction to you?

No need for that, Jim. Florida State University has done
an excellent job of explaining how wave cancellation
"redistributes" the pre-existing wave energy in "new
directions" such as the opposite direction in a
transmission line (the only other direction possible).

"... when two waves of equal amplitude and wavelength that
are 180-degrees ... out of phase with each other meet, they
are not actually annihilated, ... All of the photon energy
present in these waves must somehow be recovered or redistributed
in a new direction, according to the law of energy conservation ...

Yes, you're right, Roy. I guess I didn't consider that because I'm not very likely to buy into it, but from the point of view of someone just learning about linear systems, it's a danger.

The analogy may not be prefect, but I think it's a lot like the usefulness of the idea of a "virtual ground" at the inverting input of an op amp. But it's a virtual ground only under specific conditions: strong negative feedback is active, and the non-inverting input is at (AC, at least) ground potential. For it to be a useful concept without too many pitfalls, the person using it has to be aware that the conditions that make it a good approximation don't always hold. Similarly for a "virtual short" on a line.

Again, though, it IS useful to me to think along these lines, when looking to do something useful with stubs: I want to kill frequency W, so I can put a stub across my line that's half a wave long at W, shorted at the far end. At the same time I want to pass V, and the stub I just put there to kill W has reactance X at frequency V. If I put another stub with reactance -X at freq V across the line there, it will let V through with minimum effect. Now go calculate how well it will perform with particular lines.

So, to come up with a design to try, I do think about how stubs behave, in a general sense, including things like "a half-wave line shorted at the far end echos a short", but with the programs I have readily available, it's silly to rely on approximations that drop the line attenuation, when I want to know how my idea will actually work when I build it.

Cheers,
Tom

I want to bring up another reason to be very careful to even call them "virtual shorts." They are virtual shorts only at certain frequencies. To me, that is a very important distinction. Keeping that frequency dependence in mind helps me be ever aware that they are not anything like a real short.

> changed.

It would work, theoretically, for a small change but I doubt you'd ever
notice the effect.

You need a very directional (many elements) antenna to see a big difference
in the amount of signal in the elevation plane. High gain UHF TV antennas
do have tilters, but it's to match the angle of arrival of the signal, which
may be coming out of a duct or reflected off a nearby ridge. See a sample
at http://www.atechfabrication.com/products/atfv200_economy_tilter.htm

Most tribanders are three elements and have a 3dB beamwidth of about 60
degreees in the azimuth (plan view) plane -- worse in the elevation plane.

Further complication: The ground affects the shape of the elevation
pattern, maybe more than any tilt you could apply. You might better
fine-tune the angle of arrival by cranking a tower section up and down.

Roy Lewallen, W7EL wrote:
"If you`ll read what I`ve written, you`ll hopefully see that my only point of contention is with your claim that waves reflect from a "virtual short". They do not."

Seems to me they do.

If you are lucky enough to have a copy of Terman`s 1955 opus, we can reason together.
On page 91 is found Fig. 4-3 Vector (phasor) diagrams showing manner in which incident and reflected waves combined to produce a voltage distribution on the transmission line.

At an open circuit, the voltage phasors are in-phase.

E2, the reflected phasor, rotates clockwise as it travels back toward the source.

E1, the incident phasor, rotates counter-clockwise as we look back toward the source.

Looking 1/4-wavelength back from the open-circuit, E2 and E1, each having rotated 90-degrees, but in opposite directions, are now 180-degrees out-of-phase.

On page 92, Fig. 4-4 shows the current, which summed to zero at the open circuit, has risen to its maximum value at 1/4-wavelength back from the open-circuit while the voltage dropped to its minimum, nearly zero, maybe close enough to declare a "virtual short-circuit", 1/4-wavelength back from the open-circuit.

What`s a short-circuit? Little voltage and much current.

What`s the difference between a physical short and the virtual short? Nothing except the shunting conductor.

Is there current flowing at the open-circuit end of the 1/4-wave line segment? No, the open-circuit won`t support current.

If a high-impedance generator of the same frequency were connected to the virtual short point on the line, would it also be shorted? Yes. Where? At the virtual short, not the open-circuit at the end of the line.

It is simple inadequate models that lead to the thinking:

In the presence of mismatch, there is a reflected wave.

The anode glows red under mismatch, it obviously is caused by the power reflected from the antenna mismatch. (The observation is only made when the anode is red, so since the anode being red is always associated with a mismatch, then it is believed that mismatch always causes the anode to glow red, even though that is not a logical conclusion. The element of danger to equipment reinforces this, and elevates it to the status of a law.)

One solution is to insert an ATU near the transmitter, it works by re-reflecting the power in the reflected wave so it is all goes to antenna and totally radiated, thats what it is all about, getting all the transmitter power up the stick, how else could it work, the reflected power doesn't reach the transmitter any more. The anodes run cooler, clear proof that the explanation is sound.

ATU is really a misnomer, it doesn't tune the antenna at all (we all knew that), it is really a total-re-reflector when you have the true insight.

We have to remember that in the absence of good models of transmission line behaviour (eg quantitative models), people will try to fit models that they can understand, good or bad. If the path from mismatch to red anodes is too complicated, simplify it, leave all the intermediate explanation and conditions out, cut to the chase, what is the outcome, make it a rule.

I agree with you Roy. I think that inventing explanations that are based on things that aren't or don't happen is satisfying the learner's quest for knowledge with potentially false information that must be unlearned to move forward. Worse is that these kearners seize upon these inadequate

models and propagate them, the new experts of ham radio.

One of the risks to ham radio of the new six-hour hams is our feeding them with inappropriate and inadeqate dumbed down models. I suppose it is not new, this is probably the root of most of the myths of ham radio (eg resonant antennas always work markedly better... make it resonant and it will improve out of sight).

The killer is that word "somehow"... "all of the photon energy must somehow be redistributed".

Well of course it must! Nobody denies that conservation of energy will hold, in a system with properly defined boundaries. But the weakness of a photon model is that it cannot provide a detailed nuts-and-bolts explanation of the mechanism by which that energy becomes redistributed in time and space.

A wave model will provide all of that detail - and in transmission-line problems we can use it. If we trace what happens to forward and reflected waves of voltage (and/or current) we can predict the magnitudes and phases of those quantities at any location, at any instant. That gives us a complete time-dependent map of the voltage and current across the entire system.

From that, we can also find out where the energy is - the inputs, outputs, losses and stored energy. Sure enough, we will find that energy is conserved within the system boundaries... but that is no big deal, we always knew it would. In a wave model, conservation of energy is something you should check for, but only as an overall confirmation that you've done the sums correctly. All the useful detail came from the analysis of the voltage and/or current waves.

Not new at all... There's a huge amount of new stuff for beginners to learn, so they need simplified ideas to get them started. But it shouldn't ever have to be about unlearning. We shouldn't be feeding them false ideas that they will need to throw away completely.

Our local radio club does a lot of teaching, and at all levels we try to say: "Learn this to check the right box in the exam, but remember something else about it: it isn't a hard fact. It's actually an onion."

At the next level, we peel away a few more of the skins. The aim is always to show them how last year's simplified information fits into a bigger and deeper picture. We don't want them to throw the old information away; at the next level we want them to keep it, understand what was right about it, and also see its limitations.

At least, that's what we are aiming for. The challenge for the teacher to live up to it.

Ian,

That sounds a good approach, and it doesn't betray the trust that
learners should have in their trainers.

When ham radio is being reduced to a "communicator" hobby, it is worth
emphasising that there is great opportunity for personal development and
satisfaction in working through those layers. Some of us think that is
what ham radio is about, the ITU does, ITU-R RR Article 1 says "1.56
Amateur service: A radiocommunication service for the purpose of self-
training, intercommunication and technical investigations carried out by
amateurs, that is, by duly authorised persons interested in radio
technique solely with a personal aim and without pecuniary interest".

>. . .

Let me relate a story. . .

Years ago at Tektronix, I transferred to a different group. Across the aisle was a very bright engineer, fresh from school with a Masters or PhD degree -- I don't recall which. I recall that his advanced education had specialized in nonlinear control systems, very much a mathematically complex and challenging field. His entirely academic background had been very different from mine, so I was often enthralled by his attempts to reconcile reality with the idealized world he had, until very recently, occupied.

One day I found him muttering, trying this and that, until he asked for some help with his test setup. He was driving an inverting op amp circuit with a square wave, and he was seeing sharp pulses at the "virtual ground" summing junction with his 'scope. He had tried moving his probe grounds, replacing the op amp, bypassing, and everything else he could think of, to rid his display of this obvious erroneous artifact. The voltage at the summing junction, he explained, should always be zero, since it's a virtual ground. Those spikes shouldn't be there.

I tried to explain to him how a "virtual ground" was created: An input signal initially generates a voltage at the op amp input. The op amp responds by sending an inverted signal back to the summing junction which adds to the initial voltage to produce very nearly zero at the input. I explained that it can never be zero, but at best is the op amp output voltage divided by its open loop gain. But more to the point, the op amp isn't infinitely fast, so it takes some time for it to respond to that initial voltage or any changes. And during that lag, the summing junction voltage can move a great distance from zero. So the spikes are occurring during the time it takes the op amp to respond to changes in the input stimulus.

Well, he didn't get it. He just couldn't make the transition from the idealized, infinitely fast and infinite gain op amps of his academic models to the real things he had to work with. And looking back on it, I think the basic problem was that he never really fully understood just how that virtual ground came about even in an idealized world.

After a number more frustrating and unresolved collisions with reality, he wisely quit and got a teaching job. I'm sure he did well in the academic world.

Those many models we use daily to keep calculations, concepts, and analyses manageable are just that -- models. It's imperative to constantly be aware of the range over which those models are valid, and alert to any situation which might make the model invalid. People solving routine problems can, unfortunately, often get along for a long time without realizing the limitations of their models, and can be lulled into a belief that they're not models at all but reality. But in the environment where I've spent most of my time, this carelessness leads you very quickly into places which can be very difficult to get out of.

It is interesting to look at a single short pulse propagating along the
TL. At the stub point, the pulse must encounter a discontinuity in
impedance and therefore there will be a reflection. This can been seen
on a TDR. So there is a real reflection from a stub regardless of
whether or not it is a virtual short.

Yes, this is universally known.

> What`s a short-circuit? Little voltage and much current.

Well, at a short circuit you'll find zero volts and any current. You'll also find this at other places which aren't short circuits, such as where multiple voltage waves add to zero and at the summing junction of a perfect op amp. These aren't short circuits, but they are points of zero voltage. Saying they are all the same is like saying that because you find water in a creek, any place you find water must be a creek. What sort of logic is that?

> What`s the difference between a physical short and the virtual short?
> Nothing except the shunting conductor.

Well, yes. For one thing, waves won't reflect from a virtual short. They will, from a real short. Another difference is that a real short will prevent any waves from proceeding beyond it; they pass right through a virtual short. Good thing, too, or you wouldn't get any power to your load. Another is behavior at other frequencies and with other waveshapes. Walt has mentioned another, that a virtual short acts like a real short only in one direction, even when all the other conditions for similarity are met.

> Is there current flowing at the open-circuit end of the 1/4-wave line
> segment? No, the open-circuit won`t support current.

Correct, of course.

> If a high-impedance generator of the same frequency were connected to
> the virtual short point on the line, would it also be shorted? Yes.
> Where? At the virtual short, not the open-circuit at the end of the
> line.

Well, yes and no. When you first hook it to the virtual short, it won't be shorted -- it'll see just the Z0 of the cable. Only when its output reaches the end of the stub, reflects back, and adds to the forward wave will it be short circuited. So it's the open end of the line which is essential to creating the apparent short at the generator.

Now let us, as you say, reason together.

You're pointing out some similarities between a virtual short and a real one, and giving that as evidence that waves reflect from a virtual short. So consider a point on a 50 ohm line at which the forward and reverse waves add to a V/I of, say, 10 ohms, purely resistive to keep it simple. If you connect a generator (of the correct frequency) at that point, it will see 10 ohms after things settle down to steady state, just like your generator saw a short circuit at the "virtual short" in steady state. So can we conclude that a traveling wave will partially reflect when it encounters the 10 ohm point? The effective or "virtual" reflection coefficient can be calculated as -2/3, from which the reflected wave can be calculated. And, in fact, if we assume that such a reflection takes place, we can calculate the magnitude and phase of the

resulting wave and, sure enough, there it will really be.

But if the wave does really reflect from this "virtual discontinuity", we might have a problem. That point is a ways away from the "virtual short" point (check your Terman diagram if you don't follow), so we have a partial reflection occurring at this point as well as the full reflection from the "virtual short". In fact, unless the line is matched, we'll have reflections from every point along the line, or at best everywhere except an infinitesimally short spot every half wavelength! What a mess! Does Terman describe this problem in his book? A diagram, perhaps, showing the infinite number of partial reflections taking place all along the line?

No? Well, then, maybe it takes a perfect "virtual short" to get a reflection, and even a tiny, tiny imperfection will prevent it. So that would mean that you'd get no reflection at all from a "virtual almost-short" on even a very slightly lossy line, right? The whole idea goes to pot when you add even a tiny amount of loss? Or is a little loss ok? Then we get a full reflection from a good or pretty good "virtual short", but nothing if it gets too far from perfection. Do me a favor and check your Terman for an equation or graph which shows just where this abrupt transition point is (that is, at what "virtual resistance" the reflection ceases), and why it exists.

Help me out here with my reasoning.

Message-ID: <1176641742.157686.190690@o5g2000hsb.googlegroups.com>
Source record: 42332

I'm getting lots of noise from a local broadcaster and am looking for assistance in stopping the problem. Their freq is 1330 KHz, 5KW. They are putting out a wideband garbled signal several channels wide centered at 1120 KHz. There is a similar wideband hash up higher centered at around 1490 or so, and God only knows where else. When they play Dr. Laura on 1330, I can hear a garbled Dr. Laura all over the band. I am about 3 miles from the station but yesterday I was driving and could hear the trash 20 miles out on 1120. I've driven down I-10 in both directions from the station and their noise reaches out at least 20 miles. The station's response is that other stations also carry Dr. Laura. Please . . . . not on a dozen channels in a row with your station ID!

I've talked to the station manager several times and the engineer a couple of times and even though they will talk to me and are friendly folks, they have not fixed it. They got a new transmitter last fall and this is when it started. I've been listening here for about 30 years and this is a new problem.

I'm going to talk with the engineer one more time and then plan to write the FCC. If anyone has advice, please advise.

Thanks
Tom

That's not a killer, Ian, that's a challenge to people
like me to figure out how. If there is indeed a "somehow",
then there has to be a "how". Please don't try to dampen
my curiosity like the church priests tried to dampen Galileo's
curiosity.

I'm sure a QED explanation exists but we might have trouble
understanding it. I would like for you and others to follow
me through an energy analysis to see if you can find anything
technically wrong with it besides your revulsion to the approach.

> A wave model will provide all of that detail - and in transmission-line

> analysis of the voltage and/or current waves.

I agree with everything except your last sentence.
There is lots of useful information to be had from
tracking the energy through the system including
how and why the energy in the reflected wave changes
direction and momentum. If you think that information
doesn't matter or is not useful, then that's your
opinion. But please don't condemn the individuals who
find that information useful and go for an explanation.
And please don't say that explanation is wrong if you
cannot prove it to be invalid.

In the process of tracing forward and reflected waves,
we must remember that they obey the laws of physics
including their energy contents. The average forward energy
per unit time in a forward voltage of Vf RMS volts is
Vf^2/Z0 joules/sec, an assumption upon which the S-Parameter
analysis system is based. The average reflected energy per
unit time in a reflected RMS voltage is Vr^2/Z0 joules/sec.

In an S-Parameter analysis, if you square any of the
normalized voltage terms, you get joules/sec. Someone
said that at microwave frequencies, the powers are
often easier to measure than the voltages and currents.
The powers can be measured and the voltages and currents
calculated from the power measurements.

In optics, physicists don't have the luxury of dealing
with voltages and currents. They must necessarily deal
with energy and power. That field of physics is older
(and wiser) than RF engineering and they deal with power
reflection coefficients, not voltage reflection coefficients.

> Seems to me they do.

I wonder if we can agree that if there is no physical
impedance discontinuity, there can be no reflections?

For instance, given a piece of 50 ohm open-ended coax
with a driving source:

source-----50 ohm coax-----+---1/4WL 50 ohm coax--open

There is a virtual short at point '+' and that virtual
short exists at a point where there is no physical
impedance discontinuity. Can we agree that the forward
wave is unaffected by that virtual short? Can we agree
that the reflected wave is unaffected by that virtual
short? After all, there is absolutely nothing there
that can physically disrupt any waves.

Or given one wavelength of coax being driven by a signal
generator equipped with a circulator load.

SGCL---1/4 WL---x---1/4WL---y---1/4WL---x---1/4WL---open

There are obviously reflections at the open. Are there
any reflections at the virtual open at 'y'? Are there
any reflections at the virtual shorts at 'x'? I would
submit that in the above example, the *only* reflections
in the entire system are happening at the open end of
of the coax and that the virtual shorts and opens are
themselves effects and not the cause of anything (except
maybe arguments) :-)

current, or power would reach the load?"

No, because the example`s load is a perfect open-circuit despite Richard Clark`s disdain for good insulators. From the shorting point all the way back to the generator, the voltage distribution is unchanged, real short or virtual short. (I did not say unchanging.)

Best regards, Richard Harrison, KB5WZI

>whether or not it is a virtual short.
>Alan
>VK2ADB

I thank you for that, Alan, because, to continue, when the pulse is replaced with a sine wave, there is also a
reflection from the stub. And when going still further, since the stub presents a susceptance equal to the
line susceptance of the opposite sign at the stub point, some of the sine wave continues along the line and
reaches the mismatched termination, which also produces a real reflection. When the stub is placed at the
proper place on the line relative to the SWR (mismatch), the phase of the waves (voltage and current)
reflected from the load are opposite, respectively, to those of the waves reflected from the stub. The sum of
the voltage waves then yield a resultant reflection coefficient of 180ï¿½ and the sum of the current waves yield
a resultant of 0ï¿½, establishing a short circuit to both sets of reflected waves, but an open circuit to the
source waves.

For people who understand that fields (voltage and current) radiating from two vertical radiators that are of

the same magnitude and of opposite sign result in a null in their radiation pattern in a particular direction
must also understand that for the null to be established there must also be interaction, or interference, or
summing between the fields to cause the travel to cease in the null direction. These people also understand
that energy that was traveling in the null direction has been re-directed in another direction, raising the
level of the energy in that direction from the original level.

IMHO, these people can't have it both ways. If the fields interact, or interfere in space, such as in those
radiated from two radiators, then coherent fields traveling in a transmission line must also interact,
interfere, or sum. This is the concept on which I'm basing my impedance matching analogy using the summation
of reflection coefficients.

Walt

> reflections from a load.

Let's look at one of those reflective surfaces from
the standpoint of the forward wave in an S-Parameter
analysis.

a1---->|
|---->s21(a1)
s11(a1)<----|

a1 is the normalized forward voltage, e.g. 10
s11 is the voltage reflection coefficient, e.g. 0.707
s21 is the voltage transmission coefficient

|a1|^2 is the forward power called Pfor1 in my energy
analysis article.

|s11(a1)|^2 is the reflected power called P3 in my
energy analysis article.

|s21(a1)|^2 is the transmitted power called P1 in
my energy analysis article.

The point is that s11(a1) is a steady-state value for
normalized reflected voltage that never makes it through
the impedance discontinuity.

|s11(a1)|^2 is the steady-state reflected joules/sec
that never makes it through the impedance discontinuity.

Here is a fill in the blank question for you and anyone
else who wants to respond.

If a Z0-match exists, the above values of normalized voltage
and joules/sec do not reach the source during steady-state
because _____.

There is no doubt that Roy is absolutely wrong when he
asserts that coherent EM waves do not interact. Every
time we tune our antenna tuners to zero reflected energy,
we are causing EM waves to interact following the rules
of *linear* interference. All those waves, inductors,
and capacitors within the antenna tuner are operating
within a linear environment. If they weren't, we would
generate lots of harmonics.

Seems to me, the only valid point of argument is whether
a purely virtual impedance is a cause or an effect.

Cecil,

I pointed out a few days ago that the FSU Java applet you lean on so heavily these days is a simple tutorial device designed by a grad student and a programmer. As shown, it is physically impossible, since there is no mechanism in place to cause the waves to suddenly jump together and interfere.

It is a useful picture showing how sine waves with differing phases add together; no more and no less. It is a simple matter of mathematics. It is not a new discovery in the world of RF or optics.

Cecil,

Now that you have access to a copy of Born and Wolf, you might dig inside to see if you can improve your understanding of conservation of energy. It is not quite as simple as you seem to believe.

B&W discuss the Poynting vector and its use in an overview in the first chapter. I don't have the 4th edition. I have a couple of later editions that contain identical language, so perhaps the same thing is in the 4th edition.

In any case, here is the relevant quote. My explanations are enclosed in [...]. Otherwise the paragraph is completely intact.

"It should be noted that the interpretation of S [Poynting vector] as energy flow (more precisely as the density of energy flow) is an abstraction which introduces a certain degree of arbitrariness. For the quantity which is physically significant is, according to (41), not S itself, but the integral of S [dot] n taken over a closed surface. Clearly, from the value of the integral, no unambiguous conclusion can be drawn about the detailed distribution of S, and alternative definitions of the energy flux density are therefore possible. One can always add to S the curl of an arbitrary vector, since such a term will not contribute to the surface integral as can be seen from Gauss' theorem and the identity div curl = 0. However, when the definition has been applied cautiously, in particular for averages of small but finite regions of space or time, no contradictions with experiments have been found. We shall therefore accept the above definition in terms of the Poynting vector of the density of the energy flow."

[S and n are vectors, shown in bold type in the original.]

Now for my comments.

Two important concepts are contained in the B&W quote. First, the math involved with Poynting vectors is not quite as simple as many amateur radio operators seem to believe. It does not make any sense to simply add and subtract Poynting vectors in elementary fashion and expect to get correct results. This is true even for your favorite case of a one-dimensional problem such as a transmission line.

Second, the Poynting vector by itself means little. It is only the integral over a closed surface that has physical reality. In your favorite case of reflections and re-reflections the only useful non-trivial application of the Poynting vector would be the integration of the Poynting vector over a small region that includes the line discontinuity inside. And even then, only the total energy balance can be determined. Put in direct terms, there is no available information, and no need for any information about what happens to the energy contained in the various component waves you like to consider. It simply does not matter. The only energy balance that counts is the net energy flowing through the surface of the integration volume. Anything else is merely in your imagination. B&W allow you to add anything you like, as long as it is the curl of a vector. But there is no physical reality in doing so.

It has been pointed out numerous times that modern physical theory is correct by design. Ian again pointed out that fact earlier today. If the wave equations, the field equations, force equations, or whatever are analyzed correctly the energy balance will automatically work out correctly as well. A check of energy balance is sometimes useful to highlight any errors that might have been made in the math, but no new physical information should be expected.

Finally, it is well known by all physicists, and I believe most engineers, that energy considerations by themselves can be very useful for analyzing physical problems. Much of higher level classical mechanics and essentially all of quantum mechanics techniques are energy based. The so-called Hamiltonian formulation is well-known and widely used. It is no more or less correct than techniques based on forces and other fields, but the Hamiltonian technique is often much more computationally convenient.

Good Grief, Gene! You are arguing that because you cannot
view them in the present that they never existed in the
past. Such is nonsense.The left hand side is a historical
plot of the points of the waves before they interfere.
Of course, those points only exist back in history and
no longer exist in the present because everything in the
present is happening at a point. Do you also deny the
existence of the historical yearly temperature plot points
because they don't still exist today? Please get real.
Here's a temperature chart to which you can apply your
"impossible" logic concepts.

http://en.wikipedia.org/wiki/Global_warming

Paraphrasing your idea: "As shown, it is physically
impossible, since there is no mechanism in place to
cause more than one temperature to exist at the
present time."

That java example is an example of implementing the
S-Parameter equation b1 = s11(a1) + s12(a2) which
is CERTAINLY NOT IMPOSSIBLE. By adjusting the magnitudes
and phase angles of a1 and a2, any degree of interference
can be obtained. One wave is s11(a1) and the other wave
is s12(a2). Of course, the interference happens at a point
(or plane) so fast that it is impossible to view in real
time. But by using deductive reasoning and the known
laws of physics, we are able to come up with valid java
scripts like the above. Your confusion is in assuming
all those points have to exist simultaneously in the
present, a really, really ridiculous notion.

They do not and cannot exist simultaneously in the present
just as temperatures on a temperature plot of past years
do not and cannot exist in the present anymore. Those points
on the java script existed back in time and are plotted in
a similar manner to plotting temperatures that no longer
exist in the present.

Why don't you simply stop being such a nitwit. I understand perfectly what the Java applet is and is not. S-parameters are not a new branch of science. No one is confused except you.

Hi Jimmie,

A low halfwave operates best at 16 degrees; a quarterwave works best
in the 20s of degrees; while a 1.25 wavelength antenna works best in
the high 50s of degrees.

This presumes the last two are both ground mounted. Given that any of
these presumptions are at best a guess, then the numbers are merely
for guidance as reality may be vastly different (you really haven't
given us enough information). Actual physical size and elevation help
considerably. Also, as this is 10M, was some of the traffic from the
neighborhood (within 20 miles)?

There's the meat of the quote as far as transmission lines
are concerned. Given that transmission lines are "small but
finite regions of space or time", and since there are only
two possible directions in a transmission line, Born and
Wolf seem to give us permission to do exactly what you
are complaining about. Your concerns about light waves
in three dimensional free space just don't exist for the
primarily single dimensional "space" in a transmission line.
Ideally, the power density exists only between the inner and
outer conductors of the coax.

> It does not make any sense to simply
> add and subtract Poynting vectors in elementary fashion and expect to

The assertions that reflected waves don't exist or if they
do exist, they contain no energy, are false assertions. Trying
to sweep them under the rug by mealy-mouthing some automatic
energy balance religion is just another copout.

Before I explained it to you, you obviously had no
clue what that java script represented since you
said it was impossible. Not only is it possible,
it happens every time someone adjusts an antenna
tuner for a match.

Cecil, W5DXP wrote:
"I wonder if we can agree that if there is no physical impedance discontinuity, there can be no reflection?"

Terman says on page 118 of his 1955 opus:
"When a wave traveling along a transmission line encounters an isolated discontinuity, it is partially reflected; i.e., while a portion of the wave continues to travel down the line, another portion of the wave is reflected backwards."

On page 119 Terman says:
"A traveling wave passing through such a section (a tapered transmission line to gradually and continuously change its impedance from one value to another) will have its ratio of voltage to current transformed in accordance with the ratio of the characteristic impedances involved."

Abrupt changes in impedance are discontinuities which produce reflections. These are secondary energy sources.

Total reflection produced the wave distribution diagrammed in Fig. 4-3 on page 91, from an open-circuit on the line.

I see that a virtual short-circuit results 1/4-wave back from the open circuit and the "short" is repeated 1/2-wave back from the first virtual short. Through all the virtual shorts and opens, Terman shows the incident and reflected waves progressing unimpeded.

I believe that if a generator is connected through 1/4-wave of transmission line to a real short, 360-degrees of phase rotation presents the generator with a voltage which is almost of the same phase and magnitude as the generator`s output. Almost no current flows either into the short or back into the generator. It is similar to connecting nearly identical transformer windings in parallel.

Hybrid ring isolators are also constructed of 1/4-wave transmission line sections, and whether a port accepts or rejects energy results from voltage distributions at the ports, I think.

Best regards, Richard Harrison, KB5WZI

Suggesting that a virtual short or virtual open, by itself,
doesn't cause reflections which is what I think others are
trying to say. Reflections associated with virtual shorts
and virtual opens always occur with some extra ingredients,
like physical impedance discontinuities, the very existence
of which makes one wonder if they might somehow be
associated with the reflections. Reflections always occur
at physical impedance discontinuities.

It is exactly that kind of misleading terminology that has caused his
text to fall out of favor among many physics faculty.

> To deny the body of laws of physics regarding EM waves from
> the field of optics is an example of extreme ignorance.

You really aren't qualified to speak on behalf of the field of optics,
Cecil. You aren't quaified to speak on behalf of Eugene Hecht either,
for that matter. However, I think Dr. Hecht is still around so
perhaps you can persuade him to back you up. Be sure to ask him what
he thinks about the 4th mechanism of reflection.

Complete lack of technical content or technical defense
of your assertions is noted - nothing but a bunch of
hand-waving.

One more challenge for you, Jim. If you can prove that
an EM wave can exist without the associated ExB energy, you
will no doubt win a Nobel Prize in Physics.

Here's what Hecht says: "Any electromagnetic wave exists
within some region of space, and it is therefore natural
to consider the *radiant energy per unit volume*, or
energy density. We suppose that the electric field itself
can somehow store energy. This is a major logical step
since it imparts to the field the attribute of physical
reality - if the field has energy, it is a thing-in-itself."

Maybe it's past time for you to take that logical step
that Hecht took so long ago?

"To represent the flow of electromagnetic energy associated
with a traveling wave, let 'S' symbolize the transport of
energy per unit time (the power) across a unit area. ...
it has come to be known as the *Poynting vector*."

Hecht labels the energy per unit time in an EM wave as
"power". Hecht's Poynting vector equations contain cosine
terms. Hecht shoots down virtually every one of your
assertions and objections.

I notice you carefully avoided my S-Parameter example.

>
>Seems to me, the only valid point of argument is whether
>a purely virtual impedance is a cause or an effect.

I quote from Terman, 1947 ed. page 109:
"The distance L1 from the load, and the length 'a' of the stub, are so chosen that the reflected wave produced
by the shunting impedance of the stub is equal in magnitude and opposite in phase to the reflected wave
existing on the line at this point as a result of the reflection from the load impedance ZL. Thus, although a
reflected wave is present in the length L1 because of the reflection from ZL, there is no reflected wave on
the generator side of the stub line as a result of the cancellation of the two reflected waves."

I maintain that Terman's statements above agree precisely with my statements introducing this thread, in which
I sum the reflection coefficients of the load and stub reflections to determine the cancellation of the two
reflected waves that result in the impedance match. Call it what you like, the condition at the stub point
totally re-reflects the two sets of reflected waves, but allows total passage of the source waves through the
junction of the main line and the stub.

Seems to me that the only disagreement with my original posting is whether the condition at the stub point can
be called a 'virtual' short circuit. If I'm outvoted on that term how about selecting another term for it that
everyone can agree on. I'm sure there is no disagreement on the wave analysis of the stub

matching circuitry.

I don't know about verticals vs. beams, but certainly you can hear different areas when using a vertical or using a dipole. I've used both during numerous contests and found that from NC a dipole hears the Caribbean while a vertical hears Argentina, Brazil and points south. This is a G5RV at about 30 feet.

The beams hearing ability may wash out this difference, but the "incoming" polarity has nothing to do with the "transmitted" polarity. This is why I have both available.

Good luck,

Bill, W4WNT

> little work.

All it takes to prove you wrong is a
look at a typical S-Parameter equation involving
the superposition of two terms. In the following the
'@' sign is used for the angle sign. a1 and a2 are
normalized voltages. s21 is a transmission coefficient.
s22 is a reflection coefficient.

b2 = s21(a1) + s22(a2)

Given a1 = 10 @ 0 deg, a2 = 10 @ 180 deg,
s21 = 0.707 @ 0 deg, s22 = 0.707 @ 180 deg

s21(a1) = 0.707@0(10@0) = 7.07 @ 0 deg

s22(a2) = 0.707@180(10@180) = 7.07 @ 0 deg

superposing those two values gives:

b2 = 14.14 @ 0 deg

All is well and good. Multiply b2 by SQRT(Z0) to get
total forward voltage.

Now let's look at the powers in accordance with HP's
Ap Note 95-1. For that, we don't need to know the Z0.
The beauty of an S-Parameter analysis is that if one
squares the normalized voltages, one gets power.

|s21(a1)|^2 = 50 watts

|s22(a2)|^2 = 50 watts

|b2|^2 = 200 watts

Even in the S-Parameter analysis, superposing two 50W
waves in phase yields 200 watts. Constructive interference
not only makes it possible but demands it.

Jim, I challenge you to find anything wrong with this S-
Parameter analysis. It follows exactly Born and Wolf's
intensity equations for constructive interference when
the phase angle between a1 and a2 is 180 degrees and
their magnitudes are equal.

Roy is absolutely right, Cecil. Interact is a very poor choice of terms in this discussion. Would you assert that photons can have an effect on each other? The fact is, waves and photons can only interact with matter. If the superposition of waves actually had an effect on the waves themselves then interference patterns wouldn't look the way they do. Think about it.

I've mentioned before that readers, like a group of triaged medical patients, fall into three general categories:

1. Those who have made up their minds and won't have them changed no matter what you say or what evidence you present;
2. Those who already agree with what you're saying;
3. Those who are willing to read what you say and can be convinced.

Posting for the benefit of groups 1 and 2 is a waste of time, because there's no difference in anyone's belief or knowledge from the beginning to the end of the discussion. The third group, however, is worth while. Unfortunately, the active posters often are composed of the first two groups, and I see in this discussion that's been entirely the case. So we're left to hope that the lurkers are taking something away from this. To the lurkers out there: I hope you've read the postings, looked at the evidence, and reached some conclusions. Better yet, I hope some of you have been spurred to learn more about the topic, do some investigation of your own from reputable sources, and gain a deeper understanding of the fundamentals involved.

I see that my statements that waves don't interact with or reflect from each other in a linear medium is already being morphed into claims that I've denied that superposition happens, even though I've been careful to distinguish the two. So one final request to the lurkers: Read what I wrote, not interpretations of what I wrote.

I've tried to explain my point in about every way I know how, and further postings would just become more repetitive. So I'll bow out at this point, disappointed because I've been totally ineffectual at communicating my point to the active posters, but with hope that some of the lurkers have understood. And Walt, I'm especially disappointed that I've been unable to explain to you what I mean, because I fear that the interpretive error will detract from and reduce the credibility of your otherwise exceptional and wonderful works.

Cecil,

AN95-1 is a slide show, it is a presentation to accompany a talk, and as such is incomplete.

Another HP note is AN154 which is derived from a training seminar, but is more complete in its development. Chapter 1 is relevant to your use of S parameters.

Let me quote:

Notice that the square of the magnitude of these
new variables has the dimension of power. |a1|2
can then be thought of as the incident power on
port one; |b1|2 as power reflected from port one.
These new waves can be called traveling power
waves rather than traveling voltage waves.
Throughout this seminar, we will simply refer to
these waves as traveling waves.

It is a leap to move from "can be thought of as power" or "has the dimension of power" to your statement (which you attribute to HP AN95-1) "The beauty of an S-Parameter analysis is that if one squares the normalized voltages, one gets power." Did AN95-1 state clearly that which you suggest?

Nowhere in Chapter 1 of AN154 do they perform alegebraic operations on power, the chapter is full of expressions, but they do not use |Sxx|^2.

Roy did NOT say "interact" was a poor choice of terms. He
chose to use it as did Hecht. Hecht says waves interact.
Roy says they don't interact. I'm more likely to trust
Hecht over someone who says an S-Parameter analysis is
"gobbledigook" (sic) and doesn't even know how to
spell the word.

> Would you assert that photons can have an
> effect on each other?

Of course. Coherent photons emitted from different phased
antenna elements obviously have an effect on each other.
I suspect in addition to not understanding coherent
interference, you also don't understand coherency. When
coherent photons are traveling in the same path in the
same direction, they do not pass like ships in the night.
They affect each other. If they interfere destructively,
they redistribute some of their photonic energy in a
different direction. Every reference in the world says
that is what happens.

> The fact is, waves and photons can only
> interact with matter. If the superposition of waves actually had an
> effect on the waves themselves then interference patterns wouldn't
> look the way they do. Think about it.

I have thought long, hard, and deep about it. Wave cancellation
is prima facie evidence that coherent waves can have a permanent
effect on each other, even in free space. I don't know anything
more permanent than wave cancellation bringing both the net
E-field and the net H-field to zero.

No, not all coherent waves interfere. No, not all waves that
interfere cancel each other. Some of them do just the opposite.
But sometimes they do cancel. If you would wade through
the S-Parameter analysis with me, you would understand. An S-
parameter analysis of a Z0-match will expose the wave cancellation
toward the source for all to see. But it's rather obvious that

your mind is already made up, you think you know everything, and will stop at nothing, including character assassination, to avoid learning anything new.

How about taking the S-Parameter analysis step by step? Then you can point out the very step where I wander astray of the laws of physics.

:-) As is usual for omniscient gurus, Roy doesn't even
comprehend that there is a number 4.

4. Those who question what you say and can prove that you are
wrong.

Is it possible for Roy to be wrong? How about using standing-
wave current with its unchanging phase to try to measure the
phase shift through a loading coil? Roy actually did exactly
that and, at last assertion, defends those ignorant
measurements. He still hasn't comprehended what he did wrong.

The day a guru forgets that 4th possibility above is the
day that he becomes an obsolete historical artifact. Two
waves redistribute their energy components in different
directions. How in the world is that not interaction?

Quotes from two web pages from the field of optical engineering:

www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness
of the film are such that a phase difference exists between reflections
of p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be
zero." (Referring to 1/4 wavelength ideal thin films.)

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all 'lost' reflected intensity will appear as
enhanced intensity in the transmitted beam. The sum of the reflected and
transmitted beam intensities is always equal to the incident intensity.
This important fact has been confirmed experimentally."

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are
180-degrees ... out of phase with each other meet, they are not actually

annihilated, ... All of the photon energy present in these waves must somehow be recovered or *redistributed* in a new direction, according to the law of energy conservation ... Instead, upon meeting, the photons are *redistributed* to regions that permit constructive interference, so the effect should be considered as a *redistribution* of light waves and photon energy rather than the spontaneous construction or destruction of light."

Here is a question for Roy: Lurkers with inquiring minds want to know: How can a redistribution of energy in affected waves occur without interaction between the waves? Magic? Divine intervention? What?

The answer is "yes, they did." But, if you insist, I am willing to
change what HP said to "one gets the dimensions of power, i.e.
joules/second." As an engineer, I am content with getting close
enough but I am always agreeable to accommodating the purists.

> Nowhere in Chapter 1 of AN154 do they perform alegebraic operations on

How about Chapter 2? :-)

I will have to check out that Ap Note. In the meanwhile, maybe
you should take a look at Ap Note 95-1 from which I will quote
one example (there are others) from page 17:

|s11|^2 = Power reflected from the network input divided by Power
incident on the network input. Please adjust your thinking
to agree with HP's.

> So not you are superposing power to "yield" a resultant power.

My native language is American English but I cannot parse that
statement. Care to try again, maybe in the Queen's English? :-)

Power density can be added using the scalar intensity, irradiance,
or Poynting vector equations, but POWER CANNOT BE SUPERPOSED!!!
I don't know how many times I have to repeat that statement.

OK Jim, if that's so, then I've got to figure out a new way to explain how antenna radiation patterns are
modified by changing the relative phase of the signals fed to multiple radiators, and by changing the spacing
between the radiators. Looks like I've had it all wrong for lo these many years. I thought I've been reading
the same references as all the other posters.

thanks for the clarification
If a broadcast TX and some thing is interfering with it then on site
look for a attempted illegal connection this may sound mad but it has
happened in the UK people have tried to hi jack a TX im clutching at
straws but yiu never know.
Mike M0DMD

ps they used a dish receiver and a microwave link.

I see you corrected your English. :-) The answer is NO, powers cannot be superposed. There is a specialized equation for adding powers and it is *NOT* a superposition equation. Born and Wolf call it the "total intensity" equation with an included "interference" term. Their words, not mine.

The equation also appears in Dr. Best's QEX article of Nov/Dec 2001 and in "Optics", by Hecht.

That's correct. I said that interact is a poor choice of terms.

He
> chose to use it as did Hecht. Hecht says waves interact.

That is incorrect. Charged particles and photons interact in antennas.

And the funny thing is, you say that even you know of instances in
which the net fields are zero, and yet the waves propagate beyond that
point. You've at least seen a picture of an interference pattern,
right?

> If you would wade through

If the S parameter analysis addressed where you are going wrong, then that might be worthwhile. The problem as I said is with your idea about waves and energy. Obviously we all get the same answer at the end of the problem.

These are ground mounted monopoles and I am only talking about
skip reception. The antennas were mounted on the ground in an attempt to
eliminate as much local reception as possible. I am not too interested in
the local 10M chatter.not that there is very much but have noticed that the
two antennas talk into completely different areas on occasion. I first
noticed the phenmena back in the late sixties when I bult a 1.25 wl antena
for 11m believing that longer was always better. It was an interesting
antenna sometimes allowing me to work into canada from S Ga even when
others in the area werent even experiencing skip conditions. I was about 16
at the time but I do seem to remember that hering an opening on this antenna
meant that an opening would soon happen for the area. I was wondering if I
could duplcate the effect by tilting a yagi to a high angle. The more I
think about it I dont belive this would not be practical even if it was
possible. Not only would I have to have the antenna tipped at the right time
I would also have to have it pointed in the right direction. I would be
interested in knowing if others have experienced this effect using unually
long vertical antennas on the higher frequencies.

I guess I may have been 'intuiting' too much, myself. Since virtual
shorts and opens only appear in the steady state, I wouldn't expect
pulses to reflect off of them. I don't expect sine waves to reflect
off of them in steady state either for that matter, but that remains a
point of contention apparently.

>
> As I said, Roy is correct.

Roy is right and Hecht is wrong??? Shirley, you jest.
Remember, Roy is the guy who stands by his use of
standing wave current to measure phase shift through
a loading coil. Phase shift in standing wave current
doesn't exist in a wire or in a coil or anywhere else.

> And the funny thing is, you say that even you know of instances in
> which the net fields are zero, and yet the waves propagate beyond that

Where do the reflected waves go that propagate beyond that
point and are measured as zero amplitude by a Bird wattmeter?
Dr. Best said those zero energy canceled waves propagate right
into the source. What effect do waves of zero energy have? Are
you making that same stupid assertion? Watch out! Here comes
another one of those zero energy waves - good grief, look
at the size of that zero energy wave - it must be infinite.
What is infinity times zero? :-)

>> If you would wade through

Dear Group:
Wise words from Tom and Roy.

Roy's nincompoop was not one of my students. Last week I taught about simple op-amps and their limitations. The terms "virtual ground" and "virtual short" (as used with ideal and almost-ideal op amps) were presented only to facilitate my student's communication with others. Use of excess verbiage and names is a poor idea that should be relegated to "Social Science," some parts of which can do little other than classify. The idea that an op-amp strives to have V- be very close to V+ is clean. Following with the BW and slew rate limitations enhances the idea.

I first encountered the intransigence of labels in lieu of substance when a new faculty member. My department head went ballistic when I started a lecture on LC oscillators with the observation that they were all the same with an LCL or CLC circuit causing a necessary phase shift and that one could choose to connect to common any one of the tube's elements. Oh no, said my department head, you have to show them how a Hartley differs from a .... and he proceeded to recite the long list of named oscillators. -- I now omit the consequences of that encounter, for children may be reading and they are too young to learn the details of the blood sport known as academic politics. It took many years, but in the end I won.

Names can have great utility. Simplification is, in my experience, a necessary part of effective teaching and learning. However, I explicitly say to my students that the art of teaching engineering resides in not telling the student everything in one gulp. Current textbooks tend to present everything in one gulp.

Thus we come back to the issues at hand. Things mean just what they are defined to mean. Things are not necessarily the same as their name nor the same as things with similar names. For once, wise and good people are having a dialog. It seems to me to come down to this: "a virtual short" in a transmission line is a place where waves (current, voltage) interact to produce a small voltage and large current. A "physical short" in a transmission line is a place where a conductor (or the like) is placed such that the voltage is zero and the current is large. Most often, when "physical shorts" are found they are near the ends of transmission lines.

One characteristic of a "virtual short" is that its presence or location is dependent on frequency. Another characteristic is that signals are expected to exist on both sides of a "virtual short." One characteristic of a "physical short" is that it does not depend on frequency. Another characteristic of a "physical short" is that signals exist on only one side of the "physical short's" location.

The last seems to me to distill what is being said and what is understood. While it may not have happened to you, every time I have ventured to correct my brilliant and wise wife we have, after a while, discovered that we were in agreement all along and words were attenuating that understanding. A certain English SK would observe that an English writer of mathematics and children's books had these ideas down a long time ago.

Cecil,

You conveniently chopped out the part of the B&W quote that matters. You continue to claim that energy associated with each of the myriad of wave components that exist at the point of interest must be reconciled. The correct application of the Poynting theorem, as noted in the full B&W quote, says that your requirement is not correct. Only the net energy flow into that small integration volume has any physical reality.

Unless there is a source or sink at the point of interest, the net energy flow will be exactly zero. Further analysis is futile. Conservation of energy, specifically the Poynting theorem, does not support you or anyone else who tries to atomize the waves in an attempt to balance energy contribution from individual wave components. You are on your own.

By the way, a very similar statement about the application of Poynting vectors appears in Classical Electrodynamics by Jackson. This is not

some strange interpretation by a single author.

Cecil,

By the way, the "nitwit" comment was in reference to dragging global warming into the discussion. Just a slight bit of a diversion.

If you are looking for an opportunity to demonstrate the
veracity of your statement, 'realize' that matching the source
impedance to the line prevents re-reflection, and then be
'the first to admit it'.

Speaking of which, the global warming gurus are predicting
global chaos. The fact is that ~130K years ago, the Earth
began 10K years of global warming followed by an ice age.
The temperature 120K years ago averaged two degrees hotter
than it is today. 18K years ago, we began another 10K year
period of global warming that brought us out of the last
ice age and peaked 8K years ago two degrees hotter than it
is today. For the past 8K years, the Earth has been ever
so slowly slipping into another ice age. Al Gore knows
just about as much about global warming as you do about
destructive interference. Are you a Democrat? :-)

It happens all the time. Then people accuse me of changing
sides in the middle of an argument. I can't win.

I will admit it when you prove that "matching the source
impedance to the line" prevents reflections from the
source. You have to run bench experiments to prove
that - no 10 cent resistor hand-waving allowed.

Yes, the interference happens on all radios at all locations within 20 miles of the TX. I first heard it in my hamshack but then thought I might of had too much sensitivity and antenna there (Harris HF receiver, also IC-736) so I tried it in the car and sure enough it's bad in the car too. It's also bad in my office several miles away on a boom box.

I don't think they are broadcasting digital.

They have two towers and go directional at night. Just so happens in my direction the nighttime signal is about the same (swell).

This all happened right about the time they got the new transmitter. The engineer even offered me the old one.

Ahhh. A challenge. I like it.

But first, we need to agree on an experiment that you will
find convincing. We don't want any wiggle room after the
work is done, do we?

So I propose the following:

A signal generator with 50 Ohm output impedance is connected
to the left end of a length of 50 Ohm line and another signal
generator, also with 50 Ohm output impedance is connected to
the right end of the same line.

The signal generator on the left is set to frequency Fleft
and the one on the right is set to a different frequency
Fright. The line is appreciable fraction of 1 wavelength
long at Fleft and Fright.

Step 1 - Replace the signal generator on the right with a
50 Ohm terminator
Step 2 - Observe the signal at the left and right end of
the line. The signal at the right will be a delayed
and possibly reduced copy of the one on the left.
Step 3 - Replace the signal generator on the left with a
50 Ohm terminator.
Step 4 - Observe the signal at the right and left end of
the line. The signal at the left will be a delayed
and possibly reduced copy of the one on the right.
Step 6 - With both generators operating, observe the signal
at the left and right ends of the line.

MY expected result: If no reflections are occurring then the
signal at the left will be the sum of the signals observed at
the left in Step 2 and Step 4, while the signal at the right
will be the sum of the signals observed at the right in Step 2
and Step 4.

If any reflections have occurred, the reflection will modify
the signal at the generator end (for that particular frequency)
and MY expected result will not occur.

Does this cover it?

If MY expected result occurs, you will accept that 10 cent resistors in generators will prevent re-reflections, "realize that you are wrong and be the first to admit it."

What say ye?

No, you miss the point. You need to prove your
assertions using an ordinary commercial amateur
radio transceiver, like an IC-706.

So, out of curiosity, what do you think the outcome of my
experiment would be?

Do 10 cent resistors ever work? Or is a circulator always needed
to prevent re-reflections?

Hi Tom,

I gather this is KVOL in Lafayette. The FCC doesn't offer any
particulars about their rig, just antennas. In that regard, they may
have a bad joint in one tower that is heterodyning with another
signal.

Actually Jim, virtual shorts etc. act the same for pulse systems as for CW systems. The classic case is the rotating joint in radar systems.

Of course, real signals aren't just a single pulse but any CW signal can be represented as a series of pulses. One VNA I used years ago (Wiltron) allowed you to analyse a network by driving it with pulses , capturing the pulse or transient response and then doing a transform to go from the time domain to the frequency domain, thus producing the steady-state response. Very handy for analysing antennae in a confined space. The time window was set to exclude reflections from walls etc. so one didn't need an anechoic chamber.

But isn't that a number of cycles of RF?
Enough to reach 'steady-state'?

When I read the word 'pulse', I think rising edge, flat top,
falling edge, and the virtual short is quite different than
a real short for this signal.

> to prevent re-reflections?

Your 10 cent resistor can be thought of as a low dB
pad of sorts. It will attenuate but not eliminate
re-reflection. Again, let me remind you of Ramo &
Whinnery's warning not to attach importance to
what is calculated to happen inside an equivalent
source. There are models available for virtually
any amplifier you might choose but I don't know
how those models handle reflections.

Please wade through the S-Parameter analysis with me,
see for yourself, and suggest an alternative. The
Florida State web page says the energy involved in
wave cancellation is redistributed "somehow". Wave
cancellation is obviously not a simple reflection
from an impedance discontinuity because it does not
obey the reflection rules.

I think within the present context, we would say a CW dot
or dash has a transient response at the leading edge and
trailing edge and achieves steady-state in the middle.
I once calculated that it takes about ~30 cycles with
rho=0.707 to get very close to steady-state.

> But I still can't see that a virtual short would be
> different to a real short.

A virtual short is (Vfor-Vref)/(Ifor+Iref) = 0
where |Vfor| = |Vref|

For the virtual short to exist, two equal magnitude
EM waves have to be *flowing through* the virtual
short. EM waves *cannot flow through* a real short.

For real shorts:
V/I=0 is a result caused by the real short.

For virtual shorts:
A virtual short is a result caused by V/I=0.

I see your point. But as a CW signal can be thought of as series of
rectangular pulses,
then the effect of a virtual short/open/whatever, should be the same.
For a such a series,
the resultant signal at any point in the TL is of course quite different
from a single pulse. But I still can't see that a virtual short would be
different to a real short.

I forgot to say, the following applies only to a virtual
short in the absence of a physical impedance discontinuity.
A virtual short at a physical impedance discontinuity
involves interference between forward wave components and
reflected wave components.

Hi Alan -

Reflections measured by a TDR are caused by physical impedance
discontinuities. Virtual impedances are defined by the superposition
of forward and reflected voltages in the steady state. Pulsed systems
offer the ability to study the transient effects of a system by
viewing reflections caused only by changes in the characteristic
impedance of the transmission line. Since TDR doesn't use CW (not to
be confused with Morse Code) it does not operate under steady state
conditions and can therefore neither prove nor disprove the claim for
reflections from virtual impedances.

Hi Cecil,

I really do appreciate your courteous and patient offer. But in fact, you have already waded us through that so many times it's kinda funny that you hope it will somehow turn out differently this time. I don't understand why the S-parameter analysis is controversial - unless perhaps you're doing something fanciful with it. If not, it's no lo contendre. The point of contention is only one or two particular aspects of your energy analysis. By that I mean _your_ energy analysis, not Eugene Hechts interference equations (and poor choices of terms), not B&W's Poynting vector discussion, and not the Hewlett-Packard s-parameter application note. Although you do frequently quote, paraphrase, and presume to speak on their behalf, those people do not post your ideas to rec.radio.amateur.antenna.

I have yet to see Cecil, or anyone else, post an example of how waves can become perfectly collinear, except at an interface: a discontinuity in a transmission line, a partially-reflecting surface in an interferometer, ... -- a physical interface of some sort.

I have yet to see Cecil, or anyone else, post an example of perfectly collinear waves that perfectly cancel over some small finite volume which do not also cancel perfectly at all points up to their point of origin: a physical interface. In other words, lacking that example, I see NO physical evidence that those waves exist beyond that "point of origin." Specifically, I have not seen an example of a uniform TEM line on which it is supposed that two waves cancel perfectly over some distance, but over some other length on the same line with no interposed interfaces, the two do not perfectly cancel.

I have yet to see Cecil, or anyone else, post an example wherein the behaviour of a uniform, linear TEM transmission line is not adequately explained by the propagation constant of the line, the concept that Vf/If=-Vr/Ir=Zo, Vtotal=Vf+Vr, and Itotal=If+Ir, and the boundary conditions at any transitions or interfaces.

Whether or not any claims about power and energy formulas are accurate or not, I don't know. I'd have to be convinced they're actually useful before I looked at them more closely. So far, I've not been convinced of their utility. But then maybe I'm just slow. I could never see how the current at two ends of a wire (with no other

conductive paths between the ends) could be different unless the wire in between was storing or giving up charge, either, and I was LAUGHED AT and told that was just flat-out wrong. The laughing didn't seem to help; I still don't see it.

When I brought up that applet a few days ago, the same thing jumped out at me, and gave ME a good laugh. Yes, it shows waves cancelling, but it never shows how they got there.

Cheers,
Tom

I too purchased some of the Digicon fittings (DS6 and DS6Q) on Ebay.
Have already replaced some of my crimp-on fittings on some older RG-6
and also the new RG-6 QS, and noticed some signal improvement on a few
stations. They have completely eliminated some minor interference we
were seeing from our 30 db amp. These are great fittings, especially
for the price.

Just wanted to mention that I also got the Zenith ZDS-5061 compression
tool for $15 on Ebay, and it works great with these fittings.

Thanks again for all of the info!

Hi all,

Just got an email from SciTech Publishing about a sale linked to their 10th anniversary. Some reading this group might be interested. From their home page at http://www.scitechpub.com/, click on the link just below the banner, "RadarCon 2007 - Take advantage of our special conference prices. "

Though it's mainly books, you can also pick up WinSMITH 2.0 for $89 insead of their usual $125, I think it is, which is a discount from the "list" price of $149. There are quite a few books with "antenna" or "antennas" in the title, though most are a bit esoteric for ham use, and there are some "receiver" books. The discount is 40% from their usual prices for SciTec and Nobel titles, and 15% for others. The 15% may not be very exciting, but the 40% seems worthwhile if it's something you're looking for.

Cheers,
Tom

> grounding for an electrical system in violation of the NEC.

In violation of the NEC?? Underground metal water pipe was a required
electrode in the oldest NEC I have, 1968, and I think it has been
required since shortly after Columbus ï¿½discovered Americaï¿½.

> Also please tell
> me how you intend to prevent the scenario I discribed where the ground
> system was completely disconnected from the home when the well's metal
> plumbing was replaced with plastic.

For that very reason the NEC requires a ï¿½supplementalï¿½ electrode. As
the ï¿½NEC Handbookï¿½ makes clear, the supplemental electrode is not
required because metal water pipe is a bad electrode, only because it
may be replaced in the future by plastic.

The supplemental electrode was commonly one or two ground rods. Rods are
a little better than nothing - a rod-to-earth resistance of 25 ohms is
considered acceptable, or install 2 and resistance doesnï¿½t matter. With
a supplemental rod, if an underground metal water pipe is replaced with
plastic a good grounding electrode system becomes a poor system.

The 2005 NEC generally requires adding a ï¿½concrete encased electrodeï¿½ in
new construction . This is actually a decent electrode.

>

> be "to code" in some places but it still is not a good way to ground your
> house and definately should not be used for a lightning ground.
>

Using underground metal water pipes for grounding is ï¿½to codeï¿½ anywhere the NEC is adopted and not modified. That is a major piece of the US. The requirement to use metal water pipe as an electrode dates back a long time and is substantially unchanged. The authors of the NEC see metal underground water pipe as an effective grounding electrode. As Thomas said, ï¿½your opinion does not jibe with the National Electric Codeï¿½. You also donï¿½t say what your improvement over water pipe is.

If installing lightning rods a different NFPA standard is used. If installing a lightning rod in the form of a tower or high antenna it would also be wise to look at other standards.

Regarding corrosion, water pipe corrosion has been investigated by the International Association of Electrical Inspectors and the National Institute of Standards and Technology, and corrosion problems were found to be minimal.

I observed that Roy is absolutely right, and, that 'interact' is a
very poor choice of terms in this discussion. I said it because waves
do not, according to the definition of the word, 'act upon one
another'. That of course does not mean there isn't a net effect when
they superpose. It simply means that waves do not effect other waves.
At this point I really don't expect you to understand that.

>>> chose to use it as did Hecht. Hecht says waves interact.
>>> Roy says they don't interact.
>>
>>
>> As I said, Roy is correct.

> Roy is right and Hecht is wrong???

If Hecht actually weighed in on the subject, he would agree with Roy.
His use of the term caused you to infer something that he, I assure
you, did not intend to imply.

>> And the funny thing is, you say that even you know of instances in
>> which the net fields are zero, and yet the waves propagate beyond that
>> point.

> Where do the reflected waves go that propagate beyond that
> point and are measured as zero amplitude by a Bird wattmeter?

Take a look at the interference pattern created in space by two, separated, coherent, point sources of light. The light waves propagating from each point sources have absolutely no effect on each other as they pass through one another, alternately interfering destructively and constructively as they continue to propagate totally unaffected by the process. It doesn't matter which direction they're traveling; in no instance do waves destroy or act upon other waves, totally or partially. The result of their superposition may differ from one case to the next, but the phenomenon itself does not. But again, at this point I don't expect you to understand this.

> Dr. Best said those zero energy canceled waves propagate right
> into the source.

He might have a point. But since cancelled waves convey no energy, it doesn't really matter one way or the other, as others here have noted.

> Are
> you making that same stupid assertion?

All I'm trying to do is point out when you make a stupid assertion.

>> I think you just like to argue.
>
>

I've already made the differences as clear as I possibly can in every way I can think of, Cecil. That is why at this point I really don't expect you to understand. You could, but I think it's pretty apparent that you have too much invested in your personal theories.

Two sources impinging upon each other? If we take a specialized
example of lasers, their being bore sight in opposition. If we take
two antennas, where their -ahem- waves meet, again in opposition.
Nothing physical but the sources are required. As for perfection....

This one is extremely simple to reveal. Those familiar with
microwaves would immediately sputter "Magic T!" Tom, if you have not
seen this offered in several many posts by me, it stands to reason you
must have filters set (but how is it you are reading this?). Of
course, this like the "rat race" coupler (or hybrid ring) all share
the same dynamics. However, for the "Magic T" the cancellation port
is fed by two apparent sources wherein their phases combine to a null
(given the appropriate phases, of course) at this "point of origin."
This may beg what is meant by interface as the "Magic T" is replete in
transmission line arms - however, all are identical in characteristic
Z (a uniformity), all can be Zload matched (a uniformity which then
discards the useful illustration of cancellation), and all are TEM (a
uniformity). As for perfection....

>I have yet to see Cecil, or anyone else, post an example wherein the
>behaviour of a uniform, linear TEM transmission line is not adequately
>explained by the propagation constant of the line, the concept that Vf/

Hmmm, those filters must have been a brick wall: In times past I've
offered Soliton waves in fiber optics (TEM lines, of course) wherein
there is no dispersion as would be typically found. This, of course,
stretches the concept of "linear" TEM lines insofar as NONE are! So

much for perfection, or practicality....

>help; I still don't see it.

I don't trust claims, and measurements proving them even less so. If this statement above is about perfection; then, again, the last word has yet to be made such that accuracy can be guaranteed. [Even Ohm's law isn't accurate. Hence any power statement made in regard to it fails at some digit to the right of the decimal.]

>When I brought up that applet a few days ago, the same thing jumped
>out at me, and gave ME a good laugh. Yes, it shows waves cancelling,
>but it never shows how they got there.

When a sudden galactic Gamma burst hit us in the past, it too was of unknown origin (meaning no one knew how they got here). Later, we put up satellites to warn detectors an event was coming so we could roughly triangulate any new Gamma burst. One such event suggested a galactic black hole. Back of the envelope calculations have suggested similar Gamma burst sources (millions of light years away, but bore sight on us) could obliterate life in an entire solar systems in the space of milliseconds. Some might call that canceling waves - or a cosmic laugh.

OK, so admittedly all responses above entail exotic, rare, or strained examples. Some are ordinary within the context of experience. If all of your provisos were combined, then yes, nothing would satisify by virtue of a self-fulfilling definition.

Copy made in accordance with "Fair Use."

Hi Walt,

Your entire treatise is brilliant and useful with the one exception noted clearly above. Perhaps you could cite a single one of those references (other than Reflections of course) which directly contradicts my simple observation of an extremely well understood fundamental of nature.

Obviously a revision of that one circumstantial claim would have absolutely no impact on element spacing or how waves interfere, and it would in my view perfect the book. Once you have the currents and fields worked out properly, they look after themselves. You don't need to help them by inventing another mechanism for them to do their job. Faraday, JC Maxwell and others have already worked that out to most everyone else's satisfaction.

I think the discussion of virtual impedances and reflection coefficients is useful as an analytical tool. But it should also follow that the behavior being attributed to virtual entities is likewise, virtual i.e. it behaves as though....; that the actual cause of reflections is the real physical boundaries. That is the more reasonable approach, Walt. IMO.

Hi,

Have installad second hand gap titan DX.
Have problems to tune the antenna. If the antenna works fine voor 20 it doesn't work for 15

I have no dip at all on 40m.

The dip voor 20 is rather high in (out) the band 14600

Anyone info/tips/suggestions?

thanks, ON7RU

They can and certainly do when no energy is passing through the reflecting surface. In such a case the only energy conveyed by the wave is that which is reflected. The 100% number comes not in a single bounce, or from a single wavefront. But I don't expect you to understand this.

> The waves existed along with their energy components before
> they were canceled.

I believe your misunderstanding probably lies somewhere within that statement. It does not convey concise meaning.

> What happens to those energy components
> after the waves are canceled.

Where there are waves, there is energy. Where there are no waves, there is no energy. Show me the canceled waves.

Yeah the 1.25wl vertical want even put a signal across town on most days,
it is definatly a specialty antenna.

Best stick with transmission lines, and not lasers, but yes, you're
absolutely right. In my mind I was qualifying it as being waves
propagating in the same direction, since the discussion centers around
propagating EM cancelling out in a finite (non-zero) volume, and as
far as I know, there hasn't been anyone suggesting that waves on a
line in opposite directions cancel over a non-zero distance. I should
have explicitly stated that qualification, especially in this group.
I should, of course, also specified that all this propagation is
assumed to be in a perfectly linear medium, so someone can now offer a
transmission line made from wire wound around a ferrite core, shunted
by varicap diodes, and we'll have a nice nonlinear TEM line that all
sorts of strange things can happen on.

The "Magic T" as I know it is most certainly a physical interface in
the line. It's a four-port network. I'm surprised you'd even think
to mention it as a counter-example. Next you'll be saying that a
Michaelson interferometer (also a 4-port, where one port is commonly
terminated in a full reflection) isn't a physical interface...

Fiber optics are TEM lines??? I find lots of references to the
contrary. Can you give me any showing that they are?

I have to admit I haven't paid any attention to anything you've posted
about Soliton waves. (Do they differe from soliton waves?) Are you
saying they propagate as TEM waves in a linear medium but don't follow
the same rules with respect to linearity that other TEM waves do? Do
they not behave at boundaries in the same way that other waves do?
How do you create one in a piece of coax? I'm afraid I don't see in
what way they might be an example of something that propagates as a
TEM wave but doesn't obey the rules I'm used to seeing TEM waves obey.

No, it's about practicality. Convince me that calculations based
primarily on power (or energy) rather than on voltage and current
offer me something useful, with respect to TEM lines, and I might have
a closer look at them. I have tools that give me an accurate picture
of the distribution of voltage and current on a line as a function of
time, at any point along the line. From these, I can find the power
delivered to loads (a useful, practical quantity that I do care
about). I can calculate the power dissipated as heat as a function of
distance along the line, which in some cases is useful and practical
information. I can easily calculate the steady-state load impedance
presented to a source, given a particular line and load, and again
that's useful, practical information. Give me a practical reason for
caring about "power" in "forward" and "reverse" waves on a TEM line.

Hi Tom,

Then the challenge devolves to a self-fulfilling proposition (which may be your point at this turn) as it requires two sources to occupy the same point.

>The "Magic T" as I know it is most certainly a physical interface in
>the line. It's a four-port network. I'm surprised you'd even think
>to mention it as a counter-example. Next you'll be saying that a
>Michaelson interferometer (also a 4-port, where one port is commonly
>terminated in a full reflection) isn't a physical interface...

Again, you have a self-fulfilling proposition. This has nothing to do with obtaining a condition of interference, but about filling an impossible constraint.

Consider, you do not mention where the line begins (or ends) or otherwise constrain this physically, and yet you can easily dismiss an example out of hand. It seems it is up to the respondent to feel out these constraints, much like reading Braille on a waffle iron.

Any issue of "interface" as has been offered by quotes from Terman, or otherwise bandied about in discussion is that the "interface" presents a disturbance (a step-wise shift in characteristic Z). There is nothing, per se, about an interface that disqualifies it from the study of interference as it is quite obvious power must enter through a system through some interface.

The "Magic T" and similar devices make every effort to present a non-perturbing environment to the transmission of waves, otherwise their utility would be nil.

Also, the "Magic T" offers an excellent solution to your first issue in that it does present two sources combining at one point whereby there is total null following. There is absolutely nothing about the "Magic T" that disturbs the field with discontinuities and would appear (from the perspective of the energy) as continuous.

>Fiber optics are TEM lines??? I find lots of references to the

OK, this is foreign turf for you. I don't think offering a course on
Solitons, fiber optics and TEM waves will change the discussion here.
You asked for examples and they were provided. Do you want to further
constrain to RF below a certain frequency?

>How do you create one in a piece of coax? I'm afraid I don't see in
>what way they might be an example of something that propagates as a
>TEM wave but doesn't obey the rules I'm used to seeing TEM waves obey.

So we are now confined to coax? The refinement of constraints is
painting examples into a corner as we progress.

>
>No, it's about practicality.

Practicality when your post is littered with "perfect?" You have
rebutted every practical example offered! Do we now constrain what
practical means or is this about studying the effects of interference?

>Convince me that calculations based
>primarily on power (or energy) rather than on voltage and current
>offer me something useful, with respect to TEM lines, and I might have

Yes, I had a bit of LNBF (Late Night Brain Fade) when I threw in the rotary joint example.
What I was trying underline was that there will be a real reflection at the point where a stub is attached - simply because it becomes a discontinuity in the TL. A TDR can show this but of course, I agree that a single pulse won't see the same discontinuity as a CW.
So how does one prove or disprove the existence of a real reflection from a virtual discontinuity?
Alan

Hi Jim, not sure if my previous reply got through.
Yes, I have to admit to LNBF (Late Night Brain Fade) when I threw in the rotary joint example. Of course it is CW in the pulse. I was trying to underline that a stub puts a physical discontinuity on the TL which will give a real reflection. But as you point out, this reflection is not the same as the reflection from a virtual discontinuity for CW. However, if the CW can be thought of as a series of pulses, then does that not mean that real reflections occur and that the sum of the reflections for each pulse looks like they have come from a virtual discontinuity?
If not, how would one go about proving or disproving the idea of reflections from virtual discontinuities?
Alan

> the same point.

Well, maybe I'm mistaken, but I was under the impression that there was someone around here who was promoting the idea that two waves propagating in a linear medium could cancel over some non-zero finite volume, but not cancel everywhere along their path, even though that path was uninterrupted by any discontinuities in the medium. Maybe I'm mistaken, but I was under the impression that there was someone around here who was promoting the idea that calculations based on power rather than on voltage and current in a TEM transmission line offered some inherent value. I posted my original, "I have yet to see...," statements as a way of saying that I'm not convinced about the truth of either of those ideas, and it would go a long ways toward convincing me if someone posted examples. I'm still waiting. I still don't have a reference that a fiber optic cable is a TEM transmission line, though I have others that say that it's not. I still don't have information on whether a soliton wave can propagate in a linear medium, though I have references that say it is a non-linear phenomenon that occurs in non-linear media. If you can convince me that a wavefront coming to a Magic T doesn't see it as an impedance discontinuity, we could perhaps post more about that--or not.

But so far, your responses make me think you don't disagree with my implicit suggestions: that it's impossible to distinguish between the condition of two cancelled waves that somehow still exist (huh?) and the condition of no wave at all; and that there's precious little value in doing calculations based on "forward power" and "reverse power" in TEM lines--qualify that if you want by limiting it to the frequency range where we find it relatively easy to express what's going on in terms of voltage and current. That seems a reasonable qualification in this newsgroup.

Beyond that, you're of course welcome to go off on whatever tangents you wish. Basenote drift is the expected norm here; I engage in it all the time myself.

And I still don't exist; I'm only a figment of Cecil's imagination.

Cheers,
Tom

Please stop the unfair innuendo. You have yet to see me say that
waves can become perfectly collinear, except at an impedance
discontinuity. I have gone out of my way to say reflections
happen only at a physical impedance discontinuity. Waves become
perfectly collinear because of reflections at a physical
impedance discontinuity. I don't know how you can possibly
be confused regarding what I said.

> I have yet to see Cecil, or anyone else, post an example of perfectly
> collinear waves that perfectly cancel over some small finite volume
> which do not also cancel perfectly at all points up to their point of
> origin: a physical interface.

Please stop the unfair innuendo. You have yet to see me say that
waves do not cancel immediately at the point of reflection. That's
because they are canceled immediately, like delta-t, after the
reflection. They exist for such a short time that they cannot even
be seen on an o'scope. There existence can only be deduced because
if they didn't exist, nothing would happen at a physical impedance
discontinuity.

> I have yet to see Cecil, or anyone else, post an example wherein the

> conditions at any transitions or interfaces.

Not sure what you are getting at. All those waves are associated
with joules/second. I am not trying to replace anything. I am
merely adding an energy analysis to the voltage analysis. The
voltage analysis remains exactly the same as it has always been.

In an S-parameter analysis, if you square any of the normalized
voltage terms, you get joules/sec (power). If you square any
of the voltage reflection or transmission coefficients, you
get the power reflection coefficient. The S-Parameter analysis
seems to have been designed with power in mind. The HP Ap Note
says, "The previous four equations show that s-parameters are
simply related to power gain and mismatch loss, quantities
which ARE OFTEN OF MORE INTEREST than the corresponding

voltage functions." What do you suppose HP meant by, "ARE
OFTEN OF MORE INTEREST" regarding the power components?

Hi Alan -

The point of using pulses is that their width is short, and the time between pulses is long compared to the delay times in the system. In the case of of CW there will be standing waves all throughout the system obscuring any possible measurement of transient response. These pulses only reflect from physical discontinuities in the surge impedance of the transmission line. Otherwise, TDR would be a complete wild goose chase; a real cluster _blank_, in the vernacular of the trade.

> If not, how would one go about proving or disproving the idea of
> reflections from virtual discontinuities?
> Alan

Disproving the idea of reflections from virtual discontinuities would be done, for instance, and has been suggested, by measuring the presence of fields beyond the virtual short in a 1/4 wave stub. Finding waves reflecting instead from the open end sure would not lend support to the notion. The fact that the idea is inconsistent with Maxwell's equations doesn't help either.

I don't think there is a way to prove the idea of reflections from virtual discontinuities. But with certain specific exceptions, a system could in other ways appear to behave as though reflections are originating at virtual impedance discontinuities (+/- n half wavelengths).

Jim Kelley wrote:
> I said it because waves do
> not, according to the definition of the word, 'act upon one another'.

But they can act upon one another, Jim. The Florida State web page says so. The Melles-Groit web page says so. It says their energy components are redistributed. How can their energy components be redistributed if they have no effect on each other? You really need to join me in the s-parameter analysis.

b1 = s11(a1) + s12(a2)

That's phasor math proving that components of waves a1 and a2 have an effect on b1 and therefore on each other. Every time two coherent waves are collinear in the same direction in a transmission line, they have an effect on each other. It's called interference, either constructive or destructive.

> If Hecht actually weighed in on the subject, he would agree with Roy.

Good grief, Jim, now you are mind-fornicating Hecht. Hecht would certainly not agree with your obviously false assertions.

> His use of the term caused you to infer something that he, I assure
> you, did not intend to imply.

Your assurance and three bucks will get me a cup of Starbucks.

> Take a look at the interference pattern created in space by two,
> separated, coherent, point sources of light. The light waves
> propagating from each point sources have absolutely no effect on each
> other as they pass through one another, alternately interfering
> destructively and constructively as they continue to propagate totally
> unaffected by the process.

Yes, because they are not collinear. If they don't intersect, they also don't interfere. You can find billions of cases where they don't interfere. That doesn't mean they don't ever interfere.

Just as illustrated on the Florida State web page, when coherent waves are also collinear, as they are in a transmission line, they merge into the total wave and cease to exist as separate wave components.

b1 = s11(a1) + s12(a2)

s11(a1) and s12(a2) lose their identities and merge into b1. If your statements were true, an s-parameter analysis wouldn't

be valid but it is. Therefore, your statements are false. That's
why you need to wade through an s-parameter analysis because
you don't understand what happens or comprehend the physics
behind it.

> It doesn't matter which direction they're traveling;

On the contrary, coherent waves traveling in the same direction
in a transmission line are *collinear*. They merge and permanently
interfere with each other thus proving your strange assertions to
be false.

> I've already made the differences as clear as I possibly can in every
> way I can think of, Cecil.

But you are uttering assertions that are patently false. Given
two coherent waves traveling in the same direction in a Z0
transmission line, with equal magnitudes, V, and equal phases,
0 deg, what is the total magnitude? Do you even know how to do
phasor math?

V at 0 deg + V at 0 deg = _____

If you need help, ask your supervisor what the answer is.

Assume you are dealing with light waves in free space
instead of RF waves in a transmission line. Would you
then find intensity (power density) calculations useful?
That's why optical physicists find them so useful.

Tom, are you familiar with an s-parameter analysis?

If so, it seems to me that b1 = s11(a1) + s12(a2) = 0
represent two wave components that immediately cancel
to zero when superposed at the impedance discontinuity.
Would you care to comment?

Would you please name the person who said such. It certainly
was NOT me. The waves involved in the cancellation are
canceled so fast that they cannot be viewed on an o'scope.
But if they didn't exist, nothing would happen at an
impedance discontinuity.

Take the s-parameter equation, for instance.

b1 = s11(a1) + s12(a2) = 0

If s11(a1) doesn't exist, then s11 and/or a1 must not exist
either. But s11 and a1 can be measured. So if s11 and a1
exist, does s11(a1) exist only to be canceled or did it
never exist. If s11(a1) never existed, what the heck is
an s-parameter analysis good for?

> Maybe
> I'm mistaken, but I was under the impression that there was someone
> around here who was promoting the idea that calculations based on
> power rather than on voltage and current in a TEM transmission line
> offered some inherent value.

An energy analysis is not supposed to replace a voltage analysis
but is supposed simply to settle the question, Where does the
energy go? If we assume that in a Z0 transmission line, that
Vfor^2/Z0 = forward joules/sec and Vref^2/Z0 = reflected joules/sec,
the energy analysis falls out from the voltage analysis.

If you don't care where the energy goes, that's cool, but some
of us, like Bruene and Maxwell, do care and have been arguing
about it for decades.

To keep an energy analysis from falling out from the voltage
analysis, we have been told that reflected waves don't exist,
and if they did exist, they would be devoid of energy content.
"I have yet to see" an EM wave that can exist devoid of
energy content.

> reflections from virtual discontinuities?
> Alan

If you think of CW as a series of pulses, a "virtual short" occurs only when an inverted reflected pulse arrives at the same point at the same time as a non-inverted non-reflected pulse, causing the two to add to zero. (Or, of course, more complex combinations of multiple pulses arriving at the same point.) It isn't the same pulse which appears twice to interfere with itself; it's different pulses of the pulse string, sent at different times but arriving at the same point simultaneously due to one being delayed by reflection and the other not. So you see, the interval between those pulses is critical; if it changes, then the location of the "virtual short" changes. This is analogous to the steady state CW situation where the location of the "virtual short" changes with frequency.

In theory, you could prove that reflection isn't occurring from a "virtual discontinuity" by making an abrupt change in the excitation, for example abruptly changing its level, then noting that the effect of the change isn't seen back at the input until it propagates through the "virtual discontinuity", on to physical discontinuities where reflection actually takes place, and back. This might be difficult to do in practice, though, except with some fairly sophisticated equipment or very long lines because of the time intervals involved.

But let's suppose that you did somehow prove that a "virtual discontinuity" reflects waves. Then you have to explain the mechanism by which waves alter each other in a linear medium. Since you won't find any such mechanism described or explained in any reputable text, you'll have to come up with some pretty creative alternative physical laws or derivations on your own. They would have to explain such interesting phenomena as the diode-like nature of a "virtual discontinuity" -- that is, why the fields interact going one way and not the other. Also,

you'll need to come up with equations which take into account the infinite number of reflections from the "virtual discontinuities" which occur at nearly every point along any line not terminated in its characteristic impedance. At the end of the day, the results of those equations have to be the same as those which assume no reflections from "virtual discontinuities", because equations assuming no such reflection have been in use for over a century and have so far not been found to be in error.

Any of the proponents of "virtual discontinuity" reflections up to it?

Cecil,

Most serious calculations by optical physicists are done through
Maxwell's Equations solvers. Intensity calculations are utterly
inadequate for exploring the details of high resolution imaging, for
example.

If what you say is true, then if we measure field strengths
far enough away from an antenna to get outside the range
of interference, then all antennas are isotropic. Why don't
you call up NASA and tell them that permanent constructive
interference doesn't exist and they might as well be
using isotropic antennas?

>> It says their
>> energy components are redistributed.
>
> Which is not the same as saying waves have an effect on other waves. I
> said I didn't expect you to understand, and clearly you don't.

Well then, please explain it to me.
Here's the s-parameter equation for wave cancellation
in the b1 direction.

b1 = s11(a1) + s12(a2) = 0

s11, a1, s12, and a2 are all real measured values. b1 is a
real measured value. All of the measured values are perfectly
consistent. Exactly how did b1 get to be 0 without s11(a1) and
s12(a2) canceling each other out?

What do *you* get when you add one volt at 0 deg to one volt
at 180 deg when they are coherent and traveling in a collinear
path in a transmission line? Assuming EM waves, a value of zero
tells us that wave cancellation has occurred. So what value do
you get?

> As I said, I don't expect you to understand, and clearly here you don't.

You are a broken record, Jim, mindlessly uttering mantras to
cover up your inability to comprehend reality. I'm beginning
to understand what Roy meant by his "academic" statement.

>> Just as illustrated on the Florida State web page, when coherent

That, my friend, is permanent destructive interference, in
the flesh, as it were. One joule/second at 0 degrees plus
one joule/second at 180 degrees is indeed 0 joules/sec in
the direction of original travel of those two waves in a
transmission line. What happens after that is a two
joule/second reflection in the opposite direction away from
the impedance discontinuity that is causing the reflections
and permanent interference.

Jim, AC6XC wrote:
"Virtual impedance discontinuities do not cause reflections."

Reflection is a change in direction. On a transmission line a complete reflection is caused by a physical open or short on the line.

Current is interrupted at an open circuit. Energy in the magnetic field at the interruption collapses generating a voltage which doubles the line voltage at the open. This causes the current direction to reverse (a reverse in its phase) while not changing the phase of the voltage.

Conditions necessary for the reversal in travel direction of an EM wave are to reverse either the magnetic or electric wave`s polarization, but not to change both.

At an actual short on a line, volts are forced to zero at the short. Current doubles at the short, and the voltage wave reverses its polarization. The EM wave reverses its travel direction at the short as it did in the case of an open circuit.

When volts or amps compete against an opponent of half their magnitude, the stronger opponent wins. So, it`s volts or amps which determine which direction a wave travels on a transmission line at a discontinuity.

At a short or an open on a line , it is the current or voltage the discontinuity generates which turns the wave around. The line doesn`t care how the amps or volts came to suddenly appear at the turnaround point. If a virtual condition can generate the energy surge or escalation needed for a reversal in direction, it is as acceptable as a real discontinuity, in my opinion.

Best regards, Richard Harrison, KB5WZI

All that may be true, Gene. But don't Maxwell's
equations obey the superposition principle?
What does Maxwell say happens when we superpose
two EM waves out of phase such that destructive
interference occurs? What does Maxwell say
about the energy "lost" to destructive
interference? Where did it go?

Are intensity calculations utterly inadequate
for exploring the details of low resolution
transmission lines? :-) If the intensity
(power) calculations enumerated in the s-
parameter analysis description are utterly
inadequate, why are they used so often?

"I was trying to underline that a stub puts a physical discontinuity on
the TL which will give you a real reflection."

Short-circuited 1/4-wave stubs have long been used as "metal insulators"
to support transmission lines. This would likely be impractical if the
stubs produced a discontinuity on the line at the operatibg frequency.
The number of stubs seems without limit also. Put enough together and
you`ve constructed rectangular waveguide.

Hi Jim,
While the individual pulses are short, for them to simulate CW, they must be right next to each other. Obviously, the pulses that cancel or reinforce aren't the same ones, as Roy points out, and the CW which appears to reflect from the virtual discontinuity is the sum of all pulses, whether they are from the stub point, the other end of the stub or the load end of the TL.

> with frequency.

Hi Roy,
No disagreement with that. A single pulse will have reflections from the open end of the stub, the load end of the TL (if it's not Zo) and the stub attachment point. In a TDR, the first return will be from the latter point but it won't be of the same magnitude and sign as it would from a short. That requires all the pulses which are simulating (if you like), the CW. It will be whatever you get when the pulse, which has been happily travelling along a TL of Zo, meets a point where there are now two TLs of Zo in parallel. I consider this to be a discontinuity and will produce a real reflection albeit not, as I said, the same as that from a virtual short etc. So, in the sense that the quarter wave stub appears as a virtual short, I agree that the actual reflection to cause this comes from the open end of the stub.

Yes, you'd have to have a stub of 1/4 wave plus N 1/2 waves to see this effect. If N was large enough to see the excitation change (you could probably use a "CW pulse" a la radar to do this) I would expect to see some return from the stub attachment point, then the reflection from the open end of the stub.

That example of the non-TEM fiber optic would be rare species indeed. I've seen them, but that hardly constitutes the sole species of the breed.

>I still don't have
>information on whether a soliton wave can propagate in a linear
>medium, though I have references that say it is a non-linear
>phenomenon that occurs in non-linear media.

Of course it can propagate in a linear medium. Solitons were first reported in linear media - water - something like one hundred seventy years ago. Solitons can induce non-linearity in otherwise linear media. Solitons also interact in collision with a phase shift afterwards. Solitons have been applied to data transmission in fiber optics for a dozen years or more.

Your references are pretty sparse.

>If you can convince me
>that a wavefront coming to a Magic T doesn't see it as an impedance

Consult Terman. He is quite compelling when it comes to describing microwave plumbing. This hardly constitutes more than 4 pages total reading, if you choose to move on beyond the first page of discussion.

>But so far, your responses make me think you don't disagree with my
>implicit suggestions:

True enough to a point.

>that it's impossible to distinguish between the
>condition of two cancelled waves that somehow still exist (huh?)

The elliptical huh? seems to be a curious toe in the water for many here. Strange how a concept draws borders around energy it to make it "disappear" simply because both contributions cancel. This is like saying gravity disappears on a 1 square inch patch of earth when the falling apple has come to rest on the ground. This is also akin to the misnomer of zero-gravity environment of the astronauts in the space shuttle.

For example (drawing away from G and towards V), if I were to place two batteries in series opposition
- + + -
and connect a load to the two free terminals; sure, no current would flow because there is no potential difference, but that numerical combination doesn't make the batteries disappear. Yes, the condition is indistinguishable from a load floating in null space, but we have a priori knowledge of existing energy that informs us otherwise. If we choose to be ignorant of the knowledge in that specific locality, the map of all phase combinations around it will certainly bring it to our attention again.

>Beyond that, you're of course welcome to go off on whatever tangents
>you wish. Basenote drift is the expected norm here; I engage in it
>all the time myself.

The point of my going into a basenote drift is to present examples that demonstrate what is necessary to answer your objections (like providing two sources at one point that cancel on one side, but exist independently on the other side of an interface). If those who present their "theories" cannot meet these demonstrated characteristics, then it is reasonable to reject their claims barring their offering treatments that are equally compelling.

There are many compression tols out here. The one that I started with
is the Ideal tool. It can be gotten in any Home Depot, but it cost far
more than it's worth. I think it is still about $58, and will only
crimp one size of compression connector. The other tool I bought is
designed like the one you reference above. It has orange handles, and
can crimp RCA, BNC, and all compression connectors. I paid in the mid
$30's for mine, but I've seen them priced as high as the Ideal tool as
well.
Someone at work gave me an old compression tool that was left at there
house by a cable tech many years ago. It is very old and similar to
the Ideal tool, but not as heavy. The tool I have can crimp the short
compression connectors, as well as the long ones My tool is made by
Stern, and says Perma-Seal-II on it. It has a cutter on it, and the
extra dies to make it work with BNC, and RCA are secured to the inside
of the handle by being screwed into the inside edge. It is a great
design.

> superposition would also change. It's a completely unfounded notion,
> Cecil.

Here's an example of that "unfounded notion". Please
point out my error.

In the following example, the 100W signal generator
is equipped with a circulator load. The system is
Z0-matched during steady-state so b1 = 0 during
steady-state.

100W
SGCL--50 ohm line--x--1/2WL 291.4 ohm line--50 ohm load
a1--> b2-->
<--b1 <--a2

b1 = s11(a1) + s12(a2) b2 = s21(a1) + s22(a2)

Let t0 be the time at which the 100W forward wave
reaches point 'x' for the first time.

Just after after t0, the source signal has split
into two parts. There are as yet, no reflections,
so a2=0. Every one of these three voltages can be
measured as real. These values remain constant
throughout steady-state.

x
a1=10---->|
|---->s21(a1)=5 toward the load
s11(a1)=5<----|

Just after t0, b1=5. During steady-state, b1=0.

Please explain how b1 goes from 5 to 0 during the
transient build-up state without having s11(a1)

interact with anything. There, in a nutshell,
is your technical and logical contradiction.

> |---->s21(a1)=5 toward the load
> s11(a1)=5<----|

For those of you who are unfamiliar with the way s-parameter
voltages are normalized, here are the *actual measured*
voltages at the impedance discontinuity at t=0 + delta-t.
All three voltages can easily be seen on an o'scope a
short time after t=0. During the buildup to steady-
state Vref1 goes from 50V to 0V. How that is possible
without interaction is the question for ac6xg.

x
Vfor1=70.7V---->|
|---->120.7V=Vfor2 toward the load
Vref1=50V<----|
rho1--> | <--tau2(Vref2)=0

The corresponding equation used by RF engineers is:

Vref1 = rho1(Vfor1) + tau2(Vref2)

In this t=0 case, Vref2=0, so

Vref1 = rho1(Vfor1) at t=0

Cecil,

Changing the topic again? So soon?

You made a claim about optical physicists. I pointed out that your claim is simply not correct. You then start babbling about low resolution transmission lines. What a surprise!

You seem to be going back and forth about the utility of bringing optics into the discussion on antennas and transmission lines. I doubt that many here would expect different physical principles to apply to the two wavelength regimes. I wonder if there might be a practical reason why the preferred computational techniques are somewhat different?

The physics does not change, but the mathematical convenience does change. Yes, that seems to be a recurring theme from me.

Cecil,

Never is a long time. And I am sure you would slip away from free space or a linear medium to provide some counter example as soon as I agreed.

I agree with Jim and Roy, and most of the rest of the world. Electromagnetic waves, or photons if you prefer, simply do not interact without the assistance of interfaces, discontinuities, or a non-linear medium. Interference is a result from linear superposition. No waves are harmed in the process.

At interfaces and discontinuities lots of things can happen. There are well-established techniques for analyzing those things. There is no law of "conservation of waves", however. There is also no law that says all of the individual component waves you may choose to create need to have some sort of detailed energy balance. I have explained several times how the conservation of energy law works, but you seem to disbelieve me. (Hint: I did not make this stuff up. I gave you direct quotes from very reliable sources.)

Since you keep bringing up s-parameters, with the implication that they provide some new truth, perhaps you might go back and re-read AN-95-1.

From page 7 of the slide version:

"If other independent and dependent variables had been chosen, the network would have been described, as before, by two linear equations similar to equations 1 and 2, except that the variables and the parameters describing their relationships would be different. However, all parameter sets contain the same information about a network, and it is always possible to calculate any set in terms of any other set."

The other variables described earlier in the note include voltage and current. Again, we come to my old standby, mathematical convenience. S-parameters are very useful, but they bring nothing new to the physical

reality.

Cecil,

I am impressed! That's a pretty fancy o'scope you got. Measurement of
voltages to four significant digits at t = 0 + delta-t is definitely
world-class. That 291.4 ohm line is pretty special as well.

Is there some non-standard definition of *actual measured* that we
should consider to help interpret your results?

> Changing the topic again? So soon?

No, just asking questions, Gene, like any grasshopper worshiping at the feet of a guru is supposed to. Please stop avoiding the questions with non-technical diversions.

Do Maxwell's laws abide by the superposition principle? It is a question with a simple yes/no answer. If they do abide by the superposition principle, the forward wave and reflected wave can be analyzed separately and then superposed. Every individual wave component, e.g. s11(a1), s12(a2), s21(a2), and s22(a2) can be analyzed separately and then superposed. What do you get when you apply Maxwell's equations to s11(a1)? Hopefully, the same voltage, current, and energy as any other valid analysis. If not, there's a distinct problem that needs to be solved.

> You made a claim about optical physicists. I pointed out that your claim
> is simply not correct.

And I asked you to explain why it is not correct and you very carefully avoided answering. One wonders why.

> I doubt that
> many here would expect different physical principles to apply to the two
> wavelength regimes.

My point exactly, Gene. The two fields should agree in every way (except lingo). If you switch from voltage and current to EM fields, nothing should change. But when you admit that, you are forced to admit that voltages and currents associated with EM waves are bound by a set of restrictions, one of them being that they must at all times, travel at c(VF) and cannot, by definition, stand still as long as they exist as EM waves.

Intensity, irradiance, and Poynting vectors are just different names for the same physical phenomenon. To assert that power density in a transmission line doesn't obey the same rules as light intensity is just nonsense. The energy content of component waves has been known for decades in the field of optics and it applies just as well to RF waves as it does to light waves.

> The physics does not change, but the mathematical convenience does
> change.

My point exactly! No matter what the mathematical convenience,
(except for the lingo) the two fields should agree in every way.
When they appear to disagree, there is a contradiction somewhere.
Seems to me, in the quest to fit EM waves into the voltage and
current mold, some have forgotten that EM waves are not DC.

> harmed in the process.

"No waves are harmed in the process" implies that waves can
never be canceled. Yet, all the textbooks and all the web
pages say that when two coherent collinear waves of equal
magnitudes and opposite phases meet, they only appear to
be destroyed but their energy components are actually
"redistributed" in different directions.

That's exactly what happens to reflected waves toward the
source when a Z0-match is achieved. The energy components
in the reflected waves, s11(a1) and s12(a2), are redistributed
back toward the load. How does b1 ever go permanently to
zero without s11(a1) and s12(a2) canceling each other?

> There is also no law that says all
> of the individual component waves you may choose to create need to have
> some sort of detailed energy balance.

Yes, there is, Gene. It is called the conservation of
energy principle. You cannot create energy in one place,
have it destroyed in another place, and then argue that
everything is all right because the net energy balance
remains the same.

Then why are you so afraid to discuss an s-parameter
analysis? Please respond to my example posting. How
does s11(a1) go from 5 to 0 without interacting with
something?

> world-class. That 291.4 ohm line is pretty special as well.

Your non-technical diversions are noted. How about discussing
the technical question that was posed?

The voltages can be viewed on an o'scope. Their magnitudes
agree with the above calculated magnitudes. Do you know
of any reason that those voltages would not obey the
rules of the reflection model? When does a reflection
coefficient of 0.707 not reflect 0.707 of the incident
voltage?

The 291.4 ohm line is chosen to make rho=s11=0.707. My "450"
ohm ladder-line measures to be actually 380 ohms. Nothing
special about 291.4 ohms except that:

(291.4-50)/(291.4+50) = 0.707

We could actually design a feedline with Z0 = 291.4 ohms.
Want me to show you how? :-)

If you don't like that value, use 300 ohms and 51.5 ohms
for the coax. I'm sure between the choices of 50 ohm
coax and 52 ohm coax, there must be a 51.5 ohm coax in
there somewhere.

So give me a reference already. I find lots of references, including
ones that explain the propagation, that talk about TM, TE, hybrid, and
even quasi-TEM mode propagation in a fiber. What boundary conditions
are there in an optical fiber that give TEM mode?

>
> Your references are pretty sparse.

Yours seem non-existent. Mine at least did a good job explaining the
phenomena.

>From Wikipedia, for example, about solitons:
"The stability of solitons stems from the delicate balance of
"nonlinearity" and "dispersion" in the model equations. Nonlinearity
drives a solitary wave to concentrate further; dispersion is the
effect to spread such a localized wave. If one of these two competing
effects is lost, solitons become unstable and, eventually, cease to
exist. In this respect, solitons are completely different from "linear
waves" like sinusoidal waves. In fact, sinusoidal waves are rather
unstable in some model equations of soliton phenomena. Computer
simulations show that they soon break into a train of solitons."

There is specific mention of the Kerr effect--a nonlinearity in
optical media that support soliton transmission. One of the
references I saw specifically said that solitons are solutions to non-
linear differential equations. Since the equations governing the
behaviour of waves derive from the properties of the propagation
medium, I expect that any medium that can propagate a soliton is
nonlinear. Another reference specifically addressed the nonlinearity
of water as a transmission medium, as a necessary part of its being
able to propagate solitons.

I find nothing in the index of my "Radio Engineers' Handbook" by
Terman under either "Magic" or "Hybrid". Sorry. The three different
coaxial "Magic T" hybrid designs I DID find all do show an impedance
discontinuity: the junction of more than two lines of equal impedance
and/or impedance steps in through-lines. Sorry.

Time to move on.

Cheers,
Tom

Suppose that we have a cylindrical horn antenna with known dimensions.
Supposing that we know the generalized scattering matrix of this
cylindrical horn antenna in a given frequency. This would be a matrix
of dimensions (N+M)x(N+M) considering N modes as input and M modes as
output.
How can one extract the radiation pattern of this antenna in the given
frequency?

No one needs to replace the pipe. The system has a "supplemental"
electrode - that is why the "supplemental" electrode is REQUIRED. The
effectiveness of the grounding electrode system is reduced to what you
wanted without the water pipe. With ground rods for the "supplemental"
electrode that effectiveness is rather low. With a "concrete encased"
electrode now generally required, the effectiveness is pretty good.

Cecil,

You rarely reply directly to anything, and this is no exception. I was commenting on the *actual measurement* that you claimed. You added the emphasis, not me. Perhaps it was a *virtual measurement* instead? Do you find that you can achieve the desired results more often with such measurements?

> point out my error.

The error is not in the superposition of waves. The error is in your beliefs about the superposition of waves.

Let's take the Florida State example that you like. If I recall correctly it illustrates how two waves traveling in the same direction combine and interfere. Now if one of the waves at its peak has an amplitude of 1.0, while at that same instant the other wave has a peak amplitude of -0.5, the resultant wave will have a peak amplitude of 0.5. I hope we agree so far. Now, according to you, this process effects a change on each of the individual waves. If that is so, then please describe each of the waves after they have superposed, and detail the process by which that change took place.

Only interactions with matter can alter the characteristics of waves. That's what Maxwells equations tell us. The argument for wave-wave "interaction" is the same as the argument for reflection from virtual impedance discontinuities.

No. The fact that waves do not have an effect on other waves does not mean that their fields don't superpose.

Superposition is a mathematical as well as physical operation. You maintain that the process of adding x to y must somehow change x and y. You insist that superposing x and y means that x effects change to y, and y effects change to x. But the process of superposing x and y does not have an effect on either x or y. The only effect is we now have the algebraic sum of x and y.

Since it's easy in a lab to set up situations that clearly demonstrate that there is no echo of a transient off a "virtual short" or "virtual open", even if you could show me that miracle, it's not a miracle I could rely on. I'd forever know that I can demonstrate situations where the miracle does not occur.

Mind you, if you did show such a miracle, I'd very much want resolution between the line equations based on however far back you want to go toward Maxwell's equations (J. C. Maxwell in this case) and the "newly discovered phenomenon." In my opinion, which probably matches pretty closely with Jim's here, the fundamental line equations I know specifically disallow such a happening; at the very least we'd have to add a nonlinearity to the system. (Imagine a spark gap across the line, set off by voltage over a certain level...)

The fundamental line equations have always given me acceptable results when I deal with transmission lines. It's certainly possible that they are flawed, just as Newtonian physics is flawed. But just as we continue to use Newtonian physics in areas where we know we won't be running into, or even close to its "speed of light" or "tiny quanta of energy" limitations, I suspect we'll continue using the fundamental line equations to solve line problems in our real world. Since we have computers to handle the calculations for us easily, it seems to me there's not much reason to OVER-simplify the models we abstract from the real world problems we're trying to solve.

I see a lot of value to simplifications that let us visualize problems more clearly. I see a lot of value to modifying, or even throwing out, "classic" equations and models if we move to new ground and

discover those classic models fail. But I don't see any value in throwing out details that are easy to let a computer handle for me--in other words, in possibly simplifying a model until it is no longer accurate.

Cheers,
Tom

Hi Tom,

This is curious request indeed. Can you name any example of light
that is not TEM? Let's see, wikipedia's entry for TEM includes Fiber
Optics as example (along with the sources and illustrations for many
modes). TEM00 is the principle mode of the ubiquitous "single mode"
fiber optic that is laid in the millions of miles every year.

One vendor of Fiber modeling software
http://www.zemax.com
specifically at
http://www.zemax.com/kb/articles/154/1/How-to-Get-Real-Waveguide-Mode-Data-Into-ZEMAX/Page1.html
offers:
"ZDC thanks Steve Dods of OptiWave Corporation for supplying the
SMF-28 fiber simulation data used in this article.

"In the article How to Model Coupling Between Single-Mode Fibers
SMF-28 single mode fiber is modeled using data from the
manufacturer's datasheet. The only data provided on the optical
radiation produced at 1.31 is the mode field diameter, which is
stated to be 9.2 ï¿½ 0.4 ï¿½m.

"As a result, the fiber mode of both launch and receiver fibers
was entered as a Gaussian (TEM0,0) mode of waist 4.6ï¿½. The
resulting fiber coupling calculation agrees well with experimental
measurement."

Corning SMF-28 has been in production for nearly 20 years.

To which there is scant difference as nearly every point you recite
has already been anticipated in my earlier post (shown above). Your
rebuttal that water is non-linear is already answered in this same
quote. If this is basenote drift, we are now into the treble clef.

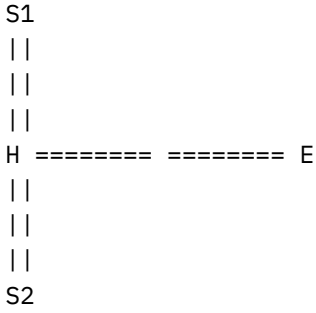
>Time to move on.

For others that are not moving on, but interested in the use and
issues of reflection to the source driving a Magic T, I quote work
from Q MEASUREMENTS FOR HIGH-Q CAVITIES
R. A. RAPUANO and J. HALPERN, MIT (1946):

"The heart of this equipment is the "magic T". This is an
eight-terminal network (Fig. 3) in waveguide or coax having
symmetry properties analogous to those of a "hybrid coil".
In the case of an ideal T, power entering the E aria is divided
equally between S1 and S2, both parts being out of phase; none
goes directly to H. Power entering the H arm is divided equally

between S1 and S2, with both parts now in phase; no power goes directly to E. Power reflected from the loads on S1 and S2, however, can be coupled from H to E, depending upon the magnitude and phase of the terminal impedances on S1 and S In the case of two short circuits the power going from H to E can be caused to vary from zero to the full amount depending on their position along the line. If a short circuit is placed on S1 and a resonant cavity is placed on S2, then the power going from H to E is a function of frequency. The power reflected back from H is the difference between the input and the loss due to transmission through E and absorption in the resonator."

Figure 3 (use fixed font):



where the interior blank space represents the plumbing too difficult to render here.

I would further offer that Walt is working on a fairly similar treatment employing the "Rat Race" (alluded to as a Hybrid Coil in the monograph extract above). The discussion above is germane in that sense and would be beneficial to those who eventually see his rebuttals to arguments pressed against him.

Richard, it really doesn't much matter to me what modes fiber optic cable supports. If there are types that support true TEM mode, I'd be happy to hear about it. So far, though, I've followed links from over a dozen searches and found NO reference that claims that true TEM mode is supported by a fiber, be it single-mode or multi-mode. I've gone to the Wikipedia pages you suggested and other pages there, and found quite a bit of info about fiber optic cables and their modes. In all that, I have found no claim that true TEM mode is supported. I followed the link you provided to the simulation software provider, and found only that they modeled a particular cable as having TEM 0,0 mode; nowhere could I see a claim that the cable modeled actually propagates by true TEM mode. The way the article was worded sounded to me like the TEM entry was an approximation. In my research, the closest to a claim of true TEM mode I've found has been in one recent article that says TEM would be the ideal, but the best anyone's been able to do is quasi-TEM or TEM-like.

You're welcome to think it's true TEM if you wish, of course, but your saying it, over and over if you wish, isn't going to be nearly as convincing as if we can find one, even one, ligitimate reference that claims true TEM.

Cheers,
Tom

Hi Tom,

What a hoot. "True" TEM? As distinct from virtual TEM? That is
about as funny as "ligitimate reference." Coining terms is a
wonderful thing if you can collect a royalty for their use.

These growing constraints have all the hallmarks of a shopping list of
suitor objections from the eternal spinster.

I reported TEM00 and offered supporting links. Just call me a liar so
I can regain my dignity. ;-)

Actually, the claim was there is reflection from a virtual discontinuity.
Almost the same thing?
I agree that there isn't in the sense that an open 1/4 wave stub looks
like a short but the reflections which appear to have come the short
actually come from the open end, but how can you introduce a stub
without also introducing a physical discontinuity which will give a real
reflection (such reflection of course, not being that which would come
from a short)?

Remembering that this conversation was about realizing mistakes,
it would be highly valuable if you were to 'realize' that you
are in error about this. If the generator output impedance is the
same as the characteristic impedance of the line, then a wave
incident upon the generator is not reflected at all. Zero.

With regards to Icom equipment, there is no dispute of the above
fact, but rather, there is dispute about whether the output
impedance of the transmitter can be characterized.

Leaving transmitters aside, it is easy to characterize the output
impedance of a generator constructed as a voltage source in
series with a resistor. The output impedance is the value of
the resistor.

> Again, let me remind you of Ramo &
> Whinnery's warning not to attach importance to
> what is calculated to happen inside an equivalent
> source.

Ramo and Whinnery's warning must be taken seriously but applies
only with reference to an equivalent circuit. If the actual
circuit is as described, then the caution does not apply.

> There are models available for virtually
> any amplifier you might choose but I don't know
> how those models handle reflections.

It is well understood in all the literature how the generator described above handles reflections. If the output impedance is the same as the characteristic impedance, then there is no reflection.

This follows from the superposition principle and its application to generators. You have indicated some reluctance to accept this, but I get the feeling you are more convinced by measurement than by theory. So I propose we continue with the experiment so that you can 'realize' that for linear generators, superposition does apply and there is no reflection from a generator whose output impedance is the same as the characteristic impedance of the line.

But we need an experiment. I have a slightly better one than previously described that you can easily replicate to convince yourself. This way you do not need to take my word for the results.

Begin by creating two files in the same directory with the content included below my signature.

Then download and install LTspice from Linear Technology:
http://www.linear.com/designtools/software/switchercad.jsp

Double click on "TLsuperposition.asc", one of the files previously created.

You will see a schematic with 3 transmission lines.

The top transmission line, 'bidirectional', has two generators attached to it; one on the left and one on the right. The TL has a 50 Ohm characteristic impedance and the two generators have 50 Ohm output impedances, easily seen from the schematic. The source in the left generator creates a 5 V, 2 MHz sine wave. The source in the right generator creates a 7 V, 3 MHz sine wave. Thus two waves are sent towards each other across the transmission line.

The second transmission line is connected to a similar generator on the left but is terminated by a resistor on the right.

The third transmission line is connected to a similar generator on the right and terminated by a resistor on the left.

If superposition holds, the observed signals at the two ends of the 'bidirectional' line will be sums of the signals at the corresponding ends of the 'left-to-right' and 'right-to-left' line.

So click Run to get some observations. Some traces appear. The first 10 microseconds are recorded and displayed.

The top pane shows the outputs of the left and right sources.

The middle pane shows the signals at the left and right ends of the bidirectional transmission line as well as the sum

of the signals at the left end of the l-to-r and r-to-l lines,
and the sum of the signals at the right end of the l-to-r
and r-to-l lines. Since some of these traces are on top of
each other, click on the signal name to bring the desired
trace to the top. They are on top of each other because
they have the same values, as expected.

The third pane shows the difference between the left end of
the bidirectional line and the sum of the left end of the other
two lines, and the same for the right. Note that the maximum
difference is around 500 nanovolts. This is not bad. Theory
says it should be zero, but given the limitations of simulation
500 nV is close enough. If this experiment were conducted with
real parts, it would be impossible to get that close.

So we have run an experiment that demonstrates the results I
expected, but results that are not consistent with your
contention. So I claim superposition holds at generators as
well as loads. Reflections do not occur even when the source
is energized.

You may like to experiment. Try different frequencies. Try
different waveshapes. Try a different length of line. Try
different source and terminating resistors. (Just remember
that you have to change the appropriate items on both the
bidirectional line and the other two for the sums to be
correct).

So what is the probability that you now 'realize' you were
wrong and '10 cent' resistors actually do eliminate reflections.

I can not emphasize enough how important this result is to
you. It will allow you to use superposition to analyze the
behaviour at the generator end and a whole class of problems
which you could not previously solve will now be solvable.

...Keith

Ouch. In TLsuperposition.asc, there are three lines that define the
transmission lines:

SYMATTR Value Td=1.1e-6 Z0=50
SYMATTR Value Td=1.1e-6 Z0=50
SYMATTR Value Td=1.1e-6 Z0=50

Looks to me like whatever technique you used to save the file
substituted
'=3d' for '='. '3d' is the ascii encoding for '=' so maybe '=' is
treated specially.

Since these are the only '='s in the file, perhaps manually editting
the '3d's
out will fix the problem.

What tools did you use to recover and save the text?

You have absolutely refused to extend that courtesy
to me so no, not until you do the same. If waves don't
diverge somewhere out there, your argument is wrong.
If they do diverge somewhere out there, they cease
to superpose. You cannot have it both ways.

Sorry, that statement is theoretical and has been proved
untrue for real-world generators unless heroic measures
are taken, e.g. circulators.

Hi all, I am just about to get my Foundation licence and am contemplating a multiband vertical. Many plan talks about "radials" being needed, now I just happen to have a house with a nice tin roof. Can I make use of the whole roof as a ground plain or do I need radials cut to resonance for each band?

Thank

Andre (vk3 - almost got it!!!)

Do you mean a trapped vertical or the like, or are you planning to use an unloaded vertical on multiple bands.

If it is a trapped vertical, it probably comes with instructions. For example, http://www.dxengineering.com/pdf/hustler_4btv5btv_instl.pdf details the installation instructions for the Huster verticals.

You could read the instructions / manual after it doesn't work properly, or you could read them beforehand.

Not all verticals require a substantial ground system, it depends on the design. The tin roof might well provide a sufficient counterpoise for some trapped verticals, depending on its size and location of the antenna.

Short verticals are invariably quite narrow band on low bands, often as little as 20kHz on 80m.

Also, keep in mind that verticals are relatively noisy in city environments.

You might be well served with a simple coax fed dipole for one band (40m) initially. Gain some experience, and note how many others are using trapped verticals or the like. Do try to resist the end fed long wire (though it is more correctly described as an end fed random length wire) that seems so popular with FLs.

A similar antenna, but one step closer to multiband operation
would be a simple dipole for one band (40m) fed with a multiple
of 1/2 wavelengths of ladder-line. At the resonant frequency,
it is hard to tell from a coax-fed dipole and an antenna
tuner will allow coverage of the entire band. The bonus is
that such an antenna can be made to work well on all ham
frequencies above the design frequency. If one is willing
to vary the length of the ladder-line, one can get by
without a conventional antenna tuner. Info at:

May I offer an example for Cecil.

Two signal generators, each with an output (source) impedance of 50
Ohms,
each connected to 0.25 wavelength of 50 Ohm line. Let us call them
North and
South with their output lines heading towards each other.

The two output lines are connected in parallel to a 3rd 50 Ohm line
heading
east that is 0.5 wavelengths long terminated in 50 Ohms.

The generators are constructed in the Thevenin style with a very low
impedance
voltage source connected in series with a 50 Ohm resistor.

Turn on the voltage source in the North generator. The wave leaves
the
generator, arriving at the joint 0.25 cycles later. Some of this wave
is
reflected and for the wave that goes through, half of it goes east
towards the load and reaches the load 0.5 cycles later, while the
other half
continues south towards the South generator which it reaches 0.25
cycles after
reaching the joint.

Since everything is terminated in 50 Ohms, there are no reflections
and the
system is in steady state 0.75 cycles after the North voltage source
is turned
on.

Turn on the South voltage source which, for interest, is 180 degrees out of
phase with the North. Heading towards the joint is a new wave which, when
it reaches the joint, some is reflected and the rest goes through splitting
between north and east. The east wave is 180 degrees out of phase with
the pre-existing wave from the North generator and cancels completely on
the East line. The other half of the wave from the South generator heads
north where it reaches the North generator after 0.25 cycles.

Again, since all lines are terminated in 50 Ohms, there are no
reflections.

0.75 cycles after the South source is turned on there is no energy left in
the East line. Where did it go? Drained by load, it was.

0.5 cycles after the South source is turned on, the North generator stops
supplying energy to the line because the voltage wave from the South is in
phase with output from the North and no current flows.

0.5 cycles after the South source is turned on, it stops supplying energy
to the line since the orignal wave from the north plus the reflection from
the joint is always equal to the source voltage so no current flows.

0.75 cycles after the South source is turned on, the system is in steady
state. The last thing that happens is that energy finishes draining from
the East line.

So it appears that two waves in the line going east are 180 degrees out
of phase and cancelling. Call this Explanation A.

Let us do the experiment in a slightly different order...

Connect only the lines going north and south, leave the line going
east disconnected.

Turn on the two sources and let the system stabilize. At the joint
between north and south will be voltage null where the voltage
is always 0. Now connect the east line to this voltage null.
Since there is 0 voltage here, there will be no waves sent down
the line so there can not be any cancellation. Call this Explanation
B.

It is important to note that the end state of the two experiments is exactly the same, and yet Explanation A has cancelling waves, while Explanation B does not.

So which explanation is CORRECT?

It is valuable to study the final state regardless of the explanation used.

In this steady state, the voltage at the joint is always 0.
This means that no energy is flowing across the joint in any direction.
(Remember energy flow is power which is volts times amps; no volts, no power).

There is no energy entering the East line. How can there be when the voltage
at the entrance is always 0.

There is no energy flowing from North to South or South to North across the
joint. (Remember P=VI and V is always 0).

There is no energy flowing out of either generator since their output currents are zero. (Remember P=VI).

There is no dissipation in either source resistor since the current through them is zero. (Remember P=VI).

Neither source is adding any energy to the system since the current from each source is zero. (Remember P=VI).

The voltage on the East line is 0 at all points.

There is a standing wave on the North-South line with a voltage null at the joint and a current null at each end.

But some will argue that there are two energy containing travelling waves going north and south despite it being clear that with a voltage of 0 in the middle of the line, no energy can be crossing this point.

Some will argue that there are two energetic waves in the east line which are cancelling despite it being clear that this depends on the order in which the connections are made.

The paradoxes. The paradoxes.

It is noted that this experiment does not use Icom transmitters, but it is believed that any wave behaviours holds for equipment other than Icom and so the experiment is still valid.

Some may argue that a perfect generator can not be constructed, but really that is a matter of cash; with enough cash one can construct a generator that is arbitrarily close to perfect. Of course the same holds for the ideal transmission lines and the terminators. The lack of absolute perfection does not obviate the value of the thought experiment for furthering understanding.

Note that the generators are fully specified so any cautions about using Thevenin or Norton equivalents do not apply since we are not dealing with equivalents.

A 1/2WL dipole is 20m on 40m and can be made to work on
all HF bands 40m-10m. That's probably what I would do
and then do something romantic to keep the XYL happy.

You can trust Owen's advice!

Here is some recommended reading on the subject from another reliable
source:

http://www.bencher.com/pdfs/00815ZZV.pdf
http://www.bencher.com/pdfs/00816ZZV.pdf

I have found Bencher's products to be a bit pricey but they are high
quality. They do have some low cost solutions.

Cushcraft is my favorite supplier because for a given type of antenna
they are the lowest cost solution. You must beware when dealing with
them that they are inclined to sell what is popular rather than what
is best for a given design.

The big problem with a multi band antenna is it is like a Swiss Army
knife. You can make it work but never as well as a single purpose
device. I find twenty meters to be the most active all-around band.

BTW, I spend more time tinkering with antennas than operating.

Congratulations on the new ticket! If you don't find what you want in
Amateur Radio you are not looking in the right place...

My antenna is similar to yours, but slightly longer. I have a 110 feet dipole running between my chimney and a tree at the back of the lot. The dipole is at a height of 30 feet and is fed with open-wire. I use an antenna tuner and the antenna works fairly well on all bands 80 through 10 meters.

But bears no resemblance to the average amateur radio
transmitter. The *goal* is to explain what happens with
the average amateur radio transmitter. We already have
signal generators with circulator loads that will do
what you are trying to do. So why bother trying to
reinvent the wheel?

So sad Cecil. If you had just popped open LTspice, you would have seen
the schematic under consideration.

But when you don't want to take a chance on learning, you can refuse
to
jump over the bar no matter how low it is, claiming it is too high.

So sad.

Your dipole is 8 feet longer than the G5RV length which
is a positive for 80m operation. For your favorite bands,
there is probably an optimum length of feedline. EZNEC
allows one to model different lengths of feedline. I
wrote a compiled BASIC DOS program that will estimate
the optimum lengths of feedline at:

I may have missed it, but to the best of my knowledge,
this is the first time you have mentioned the LTspice
reference. I apologize but I'm retired without access
to spice. Is that schematic available anywhere on the
web? If not, how about emailing me a .jpg copy of it?

What do you mean by optimum length since open-wire feedline has minimal loss? When I moved into this property last July, I just strung the longest wire that would fit into the lot, and reeled out the amount of feedline that would reach between the tuner and my shack on the second floor. I can not make the feedline appreciably shorter, and if I made it longer I would have to figure out how to support the additional feedline. I estimate the feedline has a length of 70 feet.

What length and type of feedline are you using? If ladder-
line (or similar) your have a tuned-feeder system and the
resonance frequency may not be anywhere near the stand-
alone antenna resonant frequency.

What does the antenna analyzer say is the resonant
frequency closest to 1.8 MHz?

With the two above pieces of information, we can
estimate what needs to be adjusted to obtain a
system resonance of 1.8 MHz.

You give yourself the perfect out, don't you. You won't study
the simple circuits that can be understand (for which, by the
way a circulator is not required, thus indicating that you do not
yet understand them) because they are not complicated
enough to represent an average amateur radio transmitter, and
you can't study an average amateur radio transmitter because it
is too complicated to be understood.

Conclusion: No need to study. Life is good. No need to understand.

So sad.

By "optimum length", I mean the length where you can
switch your antenna tuner into bypass mode and obtain
a 50 ohm SWR of less than ~1.6:1. For any dipole that
is 1/2WL on the lowest frequency of operation, that
will be at an SWR current maximum point making the
antenna plus tuned feeder system resonant without a tuner.

On 20m, for example, if one can vary the ladder-line
length by plus or minus 15 feet, one can always locate
the SWR current maximum point and usually bypass the
antenna tuner. I have a 20m 1/2WL dipole that I use
on 20m, 17m, 15m, 12m, 10m, and 6m without a conventional
antenna tuner by simply varying the length of the
300 ohm ladder-line.

I'm willing to study them if you will only send me a
schematic. But I'm not going to waste a lot of time
on something that is of very limited usefulness. We
already have a model that will eliminate reflections,
i.e. a signal generator equipped with a circulator,
but we don't use such for amateur radio transmitters.
Why invent something else that we don't use for amateur
radio transmitters? Why not choose an actual amateur
radio transmitter to try to understand what happens
with amateur radio transmitters? That seems like a
no-brainer to me.

I have made a indoor/outdoor STEALTH of sorts, a Multiband HF LOOP Antenna, approximately 540ft long (from center connector back around to the other side of the connector). I am using 13 gauge - copper - stranded plastic cover - wire! Does anybody have a velocity factor chart?

At the present time - my MFJ Antenna Analyser has it resonating at approx 10.5Mhz, and I am trying to get it to resonate at 1.8Mhz (160M).

I need the info to try and figure out how much I need to reduce the overall circumfrence.

Why? You say. Because if one does not understand
how the simple circuits behave, there is no hope for
understanding how something as complex as an
amateur radio transmitter behaves.

Amateur transmitters do not have circulators. If you
don't have the tools to figure out what happens when
a wave is incident on the simplest of generators (an
ideal voltage source in series with a resistor), there
is no way you can figure it out for a more complicated
transmitter.

Start simple, then extend.

To learn what happens with the simplest of generators,
look in any textbook on the subject or google '"lattice
diagram" reflection'. The LTspice simulation I previously
offerred can be used to confirm the results of analysis.

...Keith

PS - The schematic for the generator is as described above.
They are connected to each end of a transmission line as
described in a previous post. Compute how much of the

incident wave is reflected at each end. Choose any
frequency, line length, voltage and waveshape you find
convenient for the generators.

Thanks for the explanation. What you have described would be more convenient from an operating standpoint since I would have one less thing to tune during a QSY.

Hello, John,

The effect of a 1mm thick PVC coating on 1.8mm diameter of copper on
phase velocity is less then 2 percent below that of light. So c is
about 0.98...0.99*c0. This is without correction for capacitive fringing
at the ends of the wire and without correction for influence of
ground.

As your wire is about 1 wavelength for 1.8 MHz, your loop should have
a low impedance and therefore you should find a point of resonance
around 160 m band (assuming you did connect the wire directly to the
MJF). Maybe you should use a balun between your MFJ and 1WL loop.
You will get resonance at near multiples also.

Best Regards,

Wim
PA3DJS.

Actually, Keith, one of the beauties of your proposed experiment is that the line connecting the generators does NOT have to be lossless. It need only be uniform. The N-S section does not even have to be exactly 1/2 wave long; it just needs to be tapped in the center. The E-W section can be virtually any length, and it doesn't even have to have the same impedance or loss characteristics as the N-S section. The generators can be a far cry from perfect; they could just as well be ideal voltage sources, or ideal current sources, or even ICOM transmitters; they just need to be the same, and have some way to be driven out-of-phase. Using line with loss results in the sources having to deliver a small amount of power, of course, and having the N-S section differ slightly from 1/2 wavelength just means that the sources will see a slightly reactive load.

And of course, the value of your experiment is what goes on in the lines, and has nothing to do with the sources driving them. It's a beautifully simple experiment that can be produced easily on the bench, or in a simulator (like the free LTSpice or even RFSim99). Thanks for offering it, Keith.

Cheers,
Tom

Still waiting for someone to send me an ICOM 706 or whatever that was so I can measure the source impedance seen at the output terminals while it's delivering its nominally rated power to the recommended load...

Two methods I have use:

1) "Chalk line", available at any hardware store. Stretch line tight
down the center of the top of the boom (as viewed from above) snap!

2) Lay a 20 ft board, which is 1/2 dia of boom, next to boom and scribe
line down the top of the board on the boom.

I am sure there are other ways ...

I'm sorry. I must have misunderstood what you meant when you angrily insisted that waves interact. Must be one of those semantics things again. I know. Let's agree on a definition. How about the one in Merriam Websters Collegiate Dictionary, Tenth Edition:
interact: to act upon one another

> I have said just the opposite.

I must admit to not having seen that post. On the other hand I do recall seeing some where you ruthlessly insulted other people who maintained that position. I believe those are still on Google groups if you'd like to have a look back.

Tom
I was rereading this thread as to why people have a hard time in understanding Gauss's law
with respect to conservative fields and a transition to a non conservative field where with the addition of time one can consider what is outside the enclosed surface. Since you pursued the mathematical side of the subject to a minor conclusion (you stated you didn't understand what I was proposing) with John E Davis of M.I.T. I wish to share with you some notes on the Internet by David J Raymond called "a radically modern aproach"
which to me is the best I have seen on Radiation in it's entirety. Obviously there is a lot written that as hams it is not essential reading for hams but what it does do is explain in a very clear way the mechanics of radiation with specific applications with respect to the transition from conservative fields ala Gaussian law of statics to non conservative fields where at the cessation of time one can reconcile what is outside the enclosed surface with that which is inside the surface where what is inside the enclosure is in equilibrium and the enclosing surface is frictionless. As can obviously seen a Yagi inside the enclosed border cannot be considered since at the cessation of time interaction between elements is still taking place after the cessation of time. The notes are so well written that one not conversant
with upper math can still follow the implications of the discussion at hand and thus can be considered as recommended reading for all hams interested in antennas as a subject. It also gives a very clear mathematical progression from Gaussian law to the subject of non conservative fields can be formed with the activation of curl during a moment in time.
It is this progression that leads designers to design around cluster arrays that are in equilibrium regardless of orientation ie without continuing coupling effects after the cessation of time and is very well chronicalled in the above stated notes.
Best regards
Art

Hi Art,

That single, obscure, and ponderously long sentence is a clue as to
why...

>since at the cessation of time interaction between elements is still
>taking place after the cessation of time.

One has to wonder what new meaning you have for the word "cessation."

How can there be any time (for anything to take place) when there is
no more time (for anything to take place).

Forget the scribed line - what you really need is for all the holes
through the boom to be parallel. A spirit level clamped at 90deg to the
boom will achieve that.

> insisted that waves interact.

You must have indeed (deliberately?) misunderstood. If you would quote
me, as you have demanded that I quote you, you would not be so quick
to obfuscate. The key word in your statement of what I said is "must".
I have NEVER said that two waves MUST interact. All I have ever said
is that it is possible for two waves to interact. If only two waves
out of 100 trillion waves interact, then everything I have said is
true and what you have said is false.

> > I have said just the opposite.

> I must admit to not having seen that post.

It's back there somewhere but I will repeat the concept here.

1. Billions of waves don't superpose, i.e. billions of waves don't
interact.

2. Billions of waves superpose without interference, i.e. billions of
waves
don't interact.

3. Billions of waves interfere without interaction.

4. Sometimes two waves interfere with interaction between the two
waves. The interaction results in permanent change. The two reflected
waves involved in the cancellation of reflections at the surface of a
thin film cannot be recovered.

Please stop refusing to produce my postings that you are quoting as
you have a pathologicao tendency to misquote me.

Cecil, Andre will not have access to most HF bands, just 80, 40, 15, and 10m.

It takes about 6 hours to train and assess a Foundation Licencee, so your tunerless concept is perhaps more complex than Andre's current knowledge base.

For example, I worked a FL chap a couple of days ago on 40m with a 80m half wave dipole fed with a long run of coax, and he was confident that his antenna worked real well, despite my expectation that it was likely that well less than 10% of his permitted 10W PEP was radiated. It was impossible to tell this chap that if he cut the dipole to half the length it would work better on 40m.

It is no good telling people that an antenna isn't likely to work real good, they will cite all the contacts that they have had with it, and as we know, anything "works", doesn't it. However, most people listen to the positive suggestion that with change, and antenna will work better (and in the above case, more than 10 times the EIRP).

Andre, keep it simple. A coax fed half wave dipole is easy to get going will limited knowledge and experience, and you should have a high confidence that you will be able to deliver a suitable load to your transmitter (ie it will deliver its rated power), and the antenna will be quite efficient (ie that most of your 10W PEP transmitter power is radiated). It will also work well on receive.

If you hear strong FL signals around, they have good antennas, and / or are flaunting the power limit. It is easy to do the latter, but if you get the antenna right, you still have the room for improvement when you upgrade to the higher power limit.

When power supply is stopped to an array inside an enclosed surface
kinetic energy is in evidence by radiation between elements PRIOR to
emerging from the enclosed surface.
You cannot have an equation with reference to time if equality is not
obtained at the cessation of the time under consideration.
You should read up on conservative and non conservative fields before
you succumb to temptation by replying while you still have your foot
in your mouth. I have responded to you this one time only to show
others how stupid you can be when you allow animosity to over ride
cfommon sense.

Andre,

There are other options than traps, including other multiband designs that
depend on other devices to deliver a nominal 50 ohm feedpoint.

An unloaded vertical with a tuner at the base is an option.

See my earlier comment about noise in urban areas.

Your yard is obviously bigger than many suburban yards. A 40m inverted V
needs about 8m horizontally each side of the support mast.

Owen

And BTW, so are you. You ignored my earlier posting which poked holes in your model so I am going to repeat it until you respond to it. We know exactly what happens to the reflected energy when a signal generator equipped with a circulator and load are used in the following experiment.

100W SGCL----50 ohm 1/4WL stub----short

A Bird wattmeter reads 100 watts forward and 100 watts reflected. The source sources 100 watts and the circulator resistor dissipates 100 watts which is all of the reflected power.

Keith's 70.7V/50 ohm source----50 ohm 1/4WL stub----short

A Bird wattmeter reads 100 watts forward and 100w reflected. The current in the source is zero. The source is not only not sourcing any forward power, it is also not sinking any reflected power. So much for Keith's source sinking all the reflected power because it's source impedance is equal to 50 ohms, the Z0 of the transmission line.

Please don't ignore this posting like you did last time.

What is so aweful about a scribed line that leads you give an
instruction to' forget it' ?
I've never seen a 'spirit level' being used in a tool room for
accuracy nor could I specify from what you said as to why it should be
used from now on instead of conventional means.

For pleasant rag-chewing on 20 Mx, you not only need a superlative
antenna, but QRO is also recommended.

>cycle?

Now, you are talking! As the next sun spot cycle begins, the sun spot
numbers will advance rapidly and conditions will change dramatically
(fingers crossed) for the better. 17 and 15 Mx will be great
rag-chewing DX bands. At the peak of the cycle, 12 and 10 mx will be
great as well.

>I would appreciate if anyone could share experiences and ideas on this

>for my interest profile.
>
>Tnx de SM5WVN /Phil

Without a question, I would recommend a SteppIR antenna. Expensive,
but with optimal coverage from 20 mx to 6 mx. The 3 element beam is
relatively light, small and very efficient. The 4 element SteppIR
yagi is larger, heavier, more expensive and only marginally better
from a gain perspective. If you wish to cover 40 and 30 mx, there is
a version that allows dipole coverage. If you want to go all the way,

there is the MonstIR. Quite expensive, very large, very heavy and
with great coverage from 40 - 6 mx.

Wow..looks like I opened a can of worms here!
Thanks to all for the many links and advice..much food for thought. I think ill have to re assess I was considering end fed longwire also, but an inverted V might be a better option. Anyway, should be on the air within 4 weeks...the licence is the easy bit, diverting funds for the radio from the XYL is the tricky part!!! But ive been offered a FT101z , inc Yaseu Desk mix + spare set of finals (is too early to rember the number of the tubes off hand...just finished night shift), so ill have wind the wick WAY back to start with. I don't care what they say at the club...I like boat anchors!! (I'd love to replace the Murphy B40 I sold 10 years ago :-( )

Cheers

Hi Art,

Unless the enclosed surface is immense, all times (even for HF)
considered are on the scale of nanoseconds. At common excitations
considered for Amateur application would reveal power issues in the
microwatts. The ratio of scales (energy/time-volume) would be 9
orders of magnitude and well outside the accuracy of any modeler, and
vastly beyond the cares of useful theory.

It has been pointed out to me that Cecil has never used the word
'must' in the context of the above discussion. I will now rewrite my
article deleting the controversial entry . Hopefully the idea that
'waves can interact' can be safely inferred from Cecil's strenuous
argument against the report that waves don't interact.

Cecil Moore wrote:

> "No waves are harmed in the process" implies that waves can
> never be canceled.

No. The fact that waves do not have an effect on other waves does
not
mean that their fields don't superpose. [i.e. Cecil infers
incorrectly.]

Superposition is a mathematical as well as physical operation.
Because of the fact that the word interact means 'to act upon one
another', your assertion that waves can interact means
x can effect change to y, and y can effect change to x.

Since you insist that waves can have an effect on other waves, then
you should at least be able to detail either mathematically or
phenomenalogically the effect y has on x, and x has on y as well as
provide some natural process that would cause this effect. Please
elaborate. Thanks.

"still used"... I don't know that expressing reflection coefficient as gamma is an archaic notation. You see it a lot in performance specifications for RF test equipment like network analyzers. Where the magnitude is meant (and Gamma isn't real) you'd see it written with vertical bars on either side ||.

For instance, in the latest Agilent PNA manuals, they use capital Gamma.

here's an interesting interactive smith chart
http://www-ece.eng.uab.edu/JCaldwel/AgilentSmithChart/SChart.htm

lower case gamma is used for the complex propagation constant in transmission lines.

The larger efforts are done for a few reasons:
- my learning. It helps to think out the problem and attempt to
articulate it. And I have started experimenting with Spice many years
after I last tried it. It is much more usable now.
- others. I hope that there are some lurkers and others who can learn
something from the musings.
- and perhaps Cecil will learn, which would help the larger community
by reducing the amount of incorrect information being promulgated.

> By the way, when I run your LTSpice example I get 10µS of black

That usually occurs because LTSpice can not find the .plt file or it
has a syntax error. It needs to have the same name as the .asc file
and reside in the same directory. I tested by copying the content
from Google Groups. Perhaps that is a path to get the correct
content.

Well, I guess you haven't had much experience in the tool room.
Otherwise you would have been aware of how precession levels used to
set up machinery. They are used often. How do you think those long bed
lathes are adjusted so they are straight, level and parallel? Yes, my
poor misinformed person they use precession levels.

Hi Keith,

From your post:
> X: ('=B5',0,0,1e-006,1e-005)
it was the occurence of an errant B5.

You may also note similar oddities preceding your closing signature
and the substitution of B5 in the first line above for the extended
character for micro.

Your newsreader is not fully ASCII compliant. I use agent which is
totally text oriented (it does not render HTML unless so ordered).

True, except for one quibble which I will detail near the end of this
post.

Let us call this next one Experiment B.

> Keith's 70.7V/50 ohm source----50 ohm 1/4WL stub----short
>
> A Bird wattmeter reads 100 watts forward and 100w reflected. The

> Keith's source sinking all the reflected power because it's source
> impedance is equal to 50 ohms, the Z0 of the transmission line.

I have never claimed that the source in any way sank the 'reflected
power'.
I have stated that there is no re-reflection of the reflected wave at
the
source. Since the source is matched to the line, the reflection
coefficient is 0 and the wave just .... Well it must go into the
source
since tau is one. But at least it is not reflected when rho is zero.

As you observe for Experiment B, the current is zero so as you
say "The source is not only not sourcing any forward power, it is
also not sinking any reflected power."

Of course the current is also zero at the same point for
Experiment A, so there as well, the source is not only not sourcing
any forward power, it is also not sinking any reflected power.

A bit more analysis for Experiment A yields some more questions.
Terminate the line with a 50 Ohm resistor. The source is now
providing power to the line, there is no reflection on the line and
the circulator dissipates nothing.
Remove the resistor. The reflection returns. The circulator once
again dissipates 100 W. But as you said, in this condition,
"The source is not only not sourcing any forward power, it is also
not sinking any reflected power." So where did that 100 W being
dissipated in the circulator come from?

I suggest a further extension to both Experiment A and
Experiment B. Replace the 1/4 WL stub with a 1 and 1/4 WL
stub. Now, at each 1/4 WL along the line coming back from
the load, no energy is flowing because either the current is
0 or the voltage is 0. So this absence of energy flow happens
not just at the source but repeatedly along the line. This
makes it difficult to accomodate the thought that the
forward or reflected travelling waves are transporting energy
along the line (at least at the quarter wave points).

Now back to the quibble. You said: "The source sources 100 watts
and the circulator resistor dissipates 100 watts which is all of the
reflected power."

It would be more precise to say "The source sources 100 watts
and the circulator resistor dissipates 100 watts which is numerically
equal to the reflected power." I contend that it is this "numerical
equality" that has led many astray into believing that the
circulator is dissipating the "reflected power". But as we have seen,
no energy crosses the 0 current node into the generator so the
"reflected power" can not make it to the circulator (or the source
resistance, if the generator happens to have one).

> Please don't ignore this posting like you did last time.

As requested.

Oh come now Richard, the White House Science Advisor would never say that the earth is flat! Obviously our satellites and the shuttle orbit the earth. He would probably argue that it was only 4000 or so years old and that man coexisted with the dinosaurs however. And carbon dating is horribly inaccurate. And forget about all the other isotopes we use to date with, they are worthless, too.

Oh yeah, and global warming is not happening and weren't these stupid climate scientists claiming an ice age was upon us in the 70's? They just can't make up their minds and stick to it even when presented with new evidence.

Tom,
I thought I would add the following as a former mechanical engineer.
I do believe that electrical students are taught that displacement
current is some sort of electrical current when it is no such thing.
If students were taught what they read as displacement current is

really the displacement of flux under time varying conditions there would not be a barrier inferred between statics and electromagnetics. If you review what is termed as displacement current in text books and view again it in terms of flux movement during a space of time all that I am espousing will become so much clearer and understandable. Ofcourse ,those who passed exams by memory alone instead of knoweledge of first principles will never be able to understand the underlying logic to which I am referring
Regards
Art

I am appalled that I am sending such junk, but my environment is
less than it once was. Where once I had Unix and direct feed, I
am now reduced to using WinXP, Internet Explorer and Google for
posting, though I can use Outlook Express to view. I was lulled into
a false sense of security since both render the posts perfectly, but
when I save the Outlook Express, it claims to have received
text/plain but some characters have been replaced. And Google
'show original' does the same. I suppose 3 dots must mean
something to someone so it substitutes the middle one.
Agghhh.

> table . Maybe I am being to critical

Assuming you have a drill press or drill guide that allows vertical drilling, and assuming that you have at least a few feet of table, there is a solution, for VHF and up anyway.

Take a small piece of plate or board and mount a rod the same diameter as the holes you are drilling vertically from it. The accuracy here is going to set your ultimate result. If you are off 1 degree and use the device as a reference 10 times during the drilling, you will have a 10 degree twist, although there is a simple way to reduce that error.

Drill your first hole. Now use the device and the new hole to hold the boom in place and slide along your table to position your drill at the next hole. Move the device to the latest hole drilled as you run out of table. To reduce errors from imperfect vertical on the device, rotate it 180 degrees between each move.

I have used this method to drill 39 element holes for a 31 foot 432 beam with almost perfect results on an 8 foot table and just a drill guide, not a drill press. It can be used across boom diameter boundaries, which it was in this case, with a bit of care.

> . . .

I'm sure you're talking about the electromagnetic wave of E and H fields and corresponding voltages and currents. But Cecil (and, I'm afraid, others) also see waves of average power and sometimes energy, which seem to follow different rules. Just saying "wave" leaves the opportunity for misinterpretation as a wave of average power, energy, or something else, and consequent misdirection.

You may want to look at cygwin, which gives you as much unix as you
would like under windows, all the way up to X.

When you can't have the real thing, it's not a bad substitute.

Danny,
don't be silly, you obviously have not spent a lot of time in a tool
room.
A tool room machine is not in any way used as a reference level. What
is used as a reference level is the machine slide with reference to
the cutting plane. An installation of a machine is subject to settling
but it does not affect the accuracy of the product.
Use of a spirit level over the use of a straight piece of angle as a
reference plane is rather stupid and impracticable.

What complete and utter Texas-size bullsh*t. It's obvious that the
source is sourcing the forward voltage wave, and it's sucking up
entire reverse voltage wave from the line.

But the propagating waves of average power envisioned by Cecil and some others, which they measure with their Bird wattmeters, don't follow the same rules as voltage waves. Unlike voltage waves, which are very well known and subject to over a century of analysis using well established mathematics and physical principles, the waves of average power follow rules which constantly change to suit the needs of the moment. Watterson fans will recognize the rules for propagating power waves as closely resembling those of Calvinball.

It got me wondering about the advisability of buying stuff from the
west coast where the tool room machines are tested every day for
settlement for an final accuracy of plus or minus ten.
By the time they finish that review the day will be over only to start
all over again the next day.Can you imagine using a spirit level to
check for accuracy after milling a surface?

In the s-parameter equation, b1 = s11(a1) + s12(a2) = 0,
the interaction of s11(a1) and s12(a2) results in wave
cancellation. The effect of each wave on the other is
to reverse the direction and momentum of both waves.

That is what happens at a Z0-match in a transmission
line. That is what happens at the surface of thin-
film when reflections are being canceled.

Again, the redistribution of the wave energy is certainly
an interaction that wouldn't exist with either wave alone.

But you are missing the point. You say the source is matched
to the line but the source is obviously re-reflecting 100% of the
reflected energy. Your special magic source is doing exactly
the opposite of what you claim it is doing. The calculated
physical reflection coefficient may be 0 but the virtual
reflection coefficient, SQRT(Pref/Pfor), is 1.0. This is
the point I have been making ever since you started posting.

> As you observe for Experiment B, the current is zero so as you

> any forward power, it is also not sinking any reflected power.

That's again where you are wrong. In Experiment A, the circulator
load resistor is sinking 100W, i.e. 100% of the reflected power.
A bit of modulation will show that the power being sunk by the
circulator load resistor has made a round trip to the end of
the transmission line short and back.

> A bit more analysis for Experiment A yields some more questions.
> Terminate the line with a 50 Ohm resistor. The source is now

> "The source is not only not sourcing any forward power, it is also
> not sinking any reflected power." So where did that 100 W being
> dissipated in the circulator come from?

In Experiment A, the source is sourcing 100 watts and the
circulator load resistor is sinking 100 watts after the
round trip delay to the end of the line and back. If the
source signal is modulated, the delay between the source
signal and the dissipated signal is obvious and can be
measured.

> I suggest a further extension to both Experiment A and
> Experiment B. Replace the 1/4 WL stub with a 1 and 1/4 WL

> not just at the source but repeatedly along the line. This
> makes it difficult to accomodate the thought that the
> forward or reflected travelling waves are transporting energy
> along the line (at least at the quarter wave points).

The "absence of energy flow" is an illusion. There is 100
joules/sec in the forward wave and 100 joules/sec in the
reflected wave. Since the waves are flowing in opposite
directions, you can argue that there is no *net* energy
flow, but the component wave energy flow is alive and well.

> Now back to the quibble. You said: "The source sources 100 watts
> and the circulator resistor dissipates 100 watts which is all of the
> reflected power."

Yes, in Experiment A but obviously not in Experiment B.
Your source has failed to perform the way you said it would.
As I said in the beginning, there will be re-reflections from
your source. In this case, there is 100% re-reflection.
Real world conditions are not as simple-minded as you say.

> It would be more precise to say "The source sources 100 watts
> and the circulator resistor dissipates 100 watts which is numerically
> equal to the reflected power." I contend that it is this "numerical
> equality" that has led many astray into believing that the
> circulator is dissipating the "reflected power".

No, modulation on the reflected wave proves that it has made
a round trip to the end of the line and back. There is no
getting around that fact. There is also no getting around
the fact that the energy content of the stub is identical
in both experiments. The number of joules in the stub, in
both cases, is exactly the magnitude needed to support the
100W forward wave and the 100W reflected wave. The energy
in the stub in Experiment A is obviously real. The energy
in the stub in Experiment B is identical to Experiment A.

> But as we have seen,
> no energy crosses the 0 current node into the generator so the
> "reflected power" can not make it to the circulator (or the source
> resistance, if the generator happens to have one).

Your "no energy crosses the 0 current node" is just an ignorant
illusion. The forward current and reflected current are alive
and well and simply superpose to a net current of zero at that
point. We are discussing EM wave energy and a boundary condition
for EM waves to exist is that they must travel at c(VF). If they
don't, they are no longer EM waves.

At a current node, forward current equals 1.414 amps at 0 deg.
Reflected current equals 1.414 amps at 180 deg. Of course, the
net current is zero but there is no physical impedance discontinuity
to cause any change in the forward and reflected waves at that
point.

And doing it while magically expending zero energy.
Perpetual motion is possible, after all.

If zero power is being dissipated in the source, it cannot
be sourcing the forward voltage wave and it cannot be
sucking up the reverse voltage wave.

The rules of waves of average power come from the
field of optics and they haven't changed in many
decades. You see, average power is all that light
physicists can measure. They call it intensity or
irradiance. To deny the body of physics embodied
in optics is ignorant and ridiculous.

The rules for propagating waves of EM energy have been
nailed down for generations. Optical physicists don't
have the luxury of measuring voltage and current. They
must necessarily measure average power density. They
are quite good at it and their average power density
equations are quite accurate and mature. They obviously
know a lot more about EM waves than most of the posters
here.

Redistribution is an interaction....interesting. But, you were
telling us about how waves interact with other waves. I'm interested
to know what effect x has on y, and vice versa? We have x + y making
z. So after that, tell us how have x and y changed as a result of
their "interaction"?

I have tried that, and it works fine... so long as the drill stand is
fixed.

The other thing that I use that works well is a rod which I clamp to the
round stock (it is actually part of a device for hanging camping lamps
from a tent pole) and I visually line the rod up with the drill while
adjusting the angle and tightening the vice in a drill stand. The
advantage of this is that I can see the rod at the end of even 6 metres
of boom from the drill, whereas I cant see a level at great distance and
need to walk back and forwards making small adjustments.

Another variation is to drill the first hole exactly the size of some rod
(I use some 1/8" brass or stainless which I usually have on hand), fit a
short length of rod and tape it in place, then proceed as above. Then, if
necessary, drill the first hole out to the final size.

We don't usually drill the holes for an interference fit, but rather a
small clearance, so you should expect to need to align the elements after
assembly.

Hi Gene,

Good question. It was just a couple of ripples in the time-space
continuum perhaps. I can't put my finger on any commonality,
especially for the quote above when it is distinctly outside of any
association with an equal symbol.

Having patched up the text files, the modeler works quite nicely. Nice
piece of work.

It puts the popular generic title of "____ for Dummies" to the test;
because if you fill in the blank with Analog, then there is still one
dummy beneath the waves at low tide.

Ok, now that more detail unfolds, a 7MHz half wave dipole, cut to
formula, with a modest length of coax, even RG58 up to 20m in length,
will deliver most (>80%) of the transmitter power to the antenna to be
radiated, and the pi-coupled output in the '101Z will be tolerant of
the load presented to the transmitter. This is a pretty good way to
start, and you should be heard. You are about to be licenced to learn!

Unless you have an inline power meter specifically designed to measure
PEP, and that works properly, you can be assured that your PEP is less
than the maximum that the '101Z runs, which I think is close to 200W. The
tendency for FLs is to "talk it up to 10W" on an inline power meter that
doesn't respond to PEP, I call that 10 "Foundation Watts", they are not
PEP and they are not average watts, something else, but undefined since
most inline power meters don't give valid readings on anything but a
steady carrier.

If you would like to read some high level stuff about the PEP measurement
problem, see http://www.vk1od.net/VSWR/MeasureSSBTxPower.htm .

Catch you on air Andre.

You might have misunderstood Cecil. I think he is describing a system where the "optimal length" may be different on each band, so whilst you don't tune an ATU, you tune the feeder length.

Cecil will confirm or deny... Owen

I responded to this in email, but here it is for the group.

If you are using a vee block, you can place a level on the vee block
and hold it level on top of one end of the pipe. Then move to the
other end and do the same thing. Assuming you haven't moved the pipe,
you should get the holes aligned.

I just recognized you are drilling holes for elements. the above idea
or the chalkline should do you well.

Another idea would be, if you are using a drill press or a drill with
a level on it....

create your vee block to lay the pipe in to drill it. Drill the first
hole and at one end support, use a dowel or peg to hold the pipe hole
vertical. As you move the pipe along, the end support will keep the
pipe in the same position so the drill press matches all the holes.

Good luck. Let us know what method you use.

Ian I remember now from the old days. Engineers came in to the tool
room with a slide rule in their hands and the shop inspector had a
spirit level. I must have had a senior moment
Ofcourse they may even have had a plumb line int their pockets for the
bigger jobs.

> their "interaction"?

In a transmision line, when z=0, x and y are permanently
changed. Their energy components combine into one re-reflected
wave. The separate identities of x and y disappear at the
instant that z becomes zero.

In order to measure s11 and s12, a2 is turned off. The result is:

```
a1---->|
|---->s21(a2)
s11(a1)<----|
```

Note that s11(a1) has already reflected from the impedance
discontinuity and there are no other impedance discontinuities
between it and the source. Should be smooth sailing.

In order to measure s21 and s22, a1 is turned off. The result is:

```
|---->s22(a2)
s12(a2)<----|
|<----a2
```

Note that s12(a2) has already passed through the impedance
discontinuity and there are no other impedance discontinuities
between it and the source. Should be smooth sailing.

s11(a1) and s12(a2) are your two waves. They exist and are
so measurable that their measurements results in knowing
the value of s11 and s12.

For b1 = s11(a1) + s12(a2) = 0, s11(a1) and s12(a2) must
be of equal magnitude and opposite phase. That's exactly
what happens at a Z0-match.

s11(a1) and s12(a2) *never* encounter an impedance discontinuity.
They are effects of a1 and a2 encountering an impedance discontinuity.
The only thing s11(a1) and s12(a2) encounter are each other and that
interaction completely changes those two waves. The two waves cancel
and their energy components are re-distributed in the opposite
direction. s11(a1) and s12(a2) never encounter an impedance
discontinuity.

Throwing a couple of knife switches is certainly an easier
and faster QSY than rotating a coil switch and twisting
two interacting capacitor knobs.

Cecil,

Do you see the common factor in your response about "wave interaction"?
In all of your examples there is an interface or some sort of
discontinuity. Nobody argues that waves are forever unchanging. However,
those changes take place only through interaction with interfaces or
other discontinuities.

[snip]

Cecil,

You have made this claim about "component wave energy flow" or a similar claim on numerous occasions. However, only a few minutes after the message above, you wrote,

"Power and energy are scalars, Roy. Of course, scalars follow
different rules. Maybe the problem is that you are trying
to use phase math on power."

Help me out. How can we have scalars flowing in opposite directions? If the waves can interact, as you claim, why does the associated energy fail to interact and merely pass like ships in the night?

Conservation of energy does not really help the explanation in this case, as your recently discovered new reference, Principles of Optics by Born and Wolf, points out.

Cecil,

I guess you did not believe me when I said a day or two ago that optical physicists have advanced well beyond the limited capabilities you allow them. It is true that they don't measure "voltage and current". I don't even know what voltage and current mean in the standard context of optics. However, they do measure fields in many ways, and they do use extensive calculations based on fields.

The measurement tools used at optical frequencies are a bit different than the measurement tools used for RF, but they are no less capable.

Do you have any connection with "optical physicists" beyond your reading of Hecht and the Melles Griot website?

I don't disagree and I have gone on record as saying that
reflections only occur at physical impedance discontinuities.
The interaction of s11(a1) and s12(a2) is caused by the
interaction of a1 and a2 with the impedance discontinuity.
There's no doubt about that.

a1 interacts with the impedance discontinuity to cause
s11(a1) and s21(a1). a2 interacts with the impedance
discontinuity to cause s12(a2) and s22(a2). s11(a1),
s12(a2), s21(a1), and s22(a2) are created as a result
(an effect) of the interaction of a1 and a2 with the
impedance discontinuity. I have *NEVER* said that
waves interact with each other in the absence of
an impedance discontinuity. Assertions to that effect
are obfuscations of what I have said.

But even you must realize that the wave component, s11(a1),
originates traveling *away from* the impedance discontinuity
as an *EFFECT* of the forward wave, a1, being incident upon
the impedance discontinuity. It is a1 that is incident upon
the impedance discontinuity, not s11(a1). s11(a1) *originates*
at the impedance discontinuity traveling *away from* it and is
never incident upon the impedance discontinuity. All s11(a1)
ever encounters is s12(a2) and is canceled on the spot if
s12(a2) is of equal magnitude and opposite phase.

The wave component, s12(a2), *originates* at the impedance
discontinuity traveling *away from* the impedance discontinuity
as an *EFFECT* of the reflected wave, a2, being incident upon
the impedance discontinuity. It is a2 that is incident upon
the impedance discontinuity, not s12(a2). s12(a2) *originates*
at the impedance discontinuity traveling *away from* it and
is *never* incident upon the impedance discontinuity. All it
ever encounters is s11(a1) and is canceled on the spot if
s11(a1) is of equal magnitude and opposite phase.

Arguing that s11(a1) and s12(a2) are incident upon the
impedance discontinuity is obviously false since they
originate traveling *away from* the impedance discontinuity.

It is impossible for signals that originate traveling away
from the impedance discontinuity, to ever be incident upon
the impedance discontinuity. The confusing of cause and effect
is obvious.

So how do you think that signals that originate traveling
away from the impedance discontinuity ever can be incident
upon the impedance discontinuity?

> The above quote from the ARRL Antenna Book is from
> the 1988 edition.

Hmm.. yes, well fashion does change in the professional literature over time, and your citation is almost 20 years old. However, while cleaning out a lab downstairs at work, I ran across a reprint of:
Kerns, David M., "Definitions of v,i, Z, Y, a, b, Gamma, and S", Proc. IEEE, v55 n6, June 1967, pp892-900

no rhos to be found.

In another useful paper, Dybdal,R.B., Ott,R.H., "Coherent RF Error Statistics", IEEE Trans MTT, vMTT-34,n12, Dec 86
(anyone doing precision measurements on RF systems with mismatches should read this paper, if you want to get a handle on measurement uncertainties..)
Gamma is used for the reflection coefficient, and rho is used for, of all things, the phase of the reflection.

That's not to say that there's not a paper around from the 70s that uses rho.. and certainly, if you go back to the 30s and 40s, one might find rho (as a magnitude of the reflection coefficient) more commonly used, reflecting (no pun intended) the use of instruments that didn't measure phase. Precision phase measurement of reflections is a relatively recent (last 30 years?) phenomena..

So, I'll revise and say in *most current* professional literature...

Cecil, W5DXP wrote:
"The number of joules in the stub, in both cases, is exactly the magnitude needed to support the 100W forward wave and the 100W reflected wave."

An energy source of frequency f feeds a 1/4-wave short-circuited stub. The feedpoint of the stub receives a reflection from the short an instant later which is practically equal in phase and magnitude to the energy source.

How much energy will re-enter the source? Practically none because there is no difference of potential between the reflection and the source.

How much energy will continue to enter the stub? Practically none because there is no difference of potential between the source and the reflection.

Best regards, Richard Harrison, KB5WZI

Gene Fuller wrote:
> Help me out. How can we have scalars flowing in opposite directions? If
> the waves can interact, as you claim, why does the associated energy
> fail to interact and merely pass like ships in the night?

That is the nature of EM waves, Gene. EM waves flowing
in opposite directions do NOT interact. However, their
reflected and transmitted components traveling in the
same direction can and do interact at an impedance
discontinuity.

Let's take the following example using a signal generator
and 50 ohm circulator load. rho1 = s11 = 0.707

100W
SGCL---50 ohm line---+---1/2WL 291.4 ohm line---291.4 ohm load
Vfor1=70.7V--> Vfor2=120.7V-->
<--Vref1=50V <--Vref2=0V

Vref1 is the reflected wave that *originates* traveling toward
the source. Its power gets dissipated in the circulator load
resistor. It *NEVER* travels toward the impedance discontinuity.

Vref1 = 0.707(70.7V) = 50V This is the wave that we have
to cancel when we switch the load to 50 ohms. This wave
gets canceled without ever encountering an impedance
discontinuity.

Would you please explain how a wave that originates traveling
away from the impedance discontinuity ever encounters the
impedance discontinuity?

I know that, Gene. What I have been describing is a history
of the physics of optics. When the theories were first being
developed, all optical physicists could so was measure the
average power density of the light waves. The theories
based on those average power density measurements are
still good today so they must have known what they were
doing. However, if you would like to discredit those great
optical physicists, based on the better measurement
techniques available today, be my guest.

Cecil, I was thinking of trying your no= tune antenna and the 16 ft piece
may not be doable at my QTH, I have to keep it all hidden behind the bushes.
Could this piece be replaced with a circuit using lumped LC values.

It certainly is an interesting way of looking at things, Cecil. It's certainly true that equal and opposite fields cancel. When that's the case though it becomes problematic arguing that there are waves there. Did you ever see the movie "A Brilliant Mind" by any chance?

Yes, the reflected wave from 50 ohm coax trying to enter Keith's
50 ohm transmitter will be 100% re-reflected in a lossless stub
in complete violation of his assertions which proves that the
reflected wave doesn't see the source impedance and instead sees
the source load-line impedance.

> How much energy will continue to enter the stub? Practically none
> because there is no difference of potential between the source and the
> reflection.

In a lossless stub, zero energy will continue to enter the stub.
In fact, in a lossless stub, the source can theoretically be
completely disconnected and everything remains the same
including 100% re-reflection of reflected waves by the new
open circuit.

Of course, if the stub is real, the losses will take everything
to zero if the stub is disconnected because the source is
supplying the small amount of power lost to dissipation in
a real-world stub which doesn't have an infinite impedance.

Hi Jimmie,

I've been doing it with a binary switched coax matcher for 15 years.
It occupies about half a cubic foot and tunes in increments of 1, 2,
4, 8, and 16 feet.

That would work at one frequency but not others. What I do with
the 16 foot length is coil it into a spiral of 4 turns. The
diameter of the spiral is about 16 inches and the overall
length of the spiral is about 24 inches. That should fit
"behind the bushes". I use a piece of fiberglass rod to
which to tiewrap the coils.

There's nothing magic about the 16 foot length. It is only
necessary if you need to vary your length from 0 to 31 feet.
In actual practice with my 130 foot dipole, I only needed
to vary the length from 0 to 23 feet so I made the "16 ft"
section just another 8 foot section. The 16 foot section
was required from 3.5-3.6 MHz and I never use those frequencies.
That's why I could get away with replacing the 16 ft section
with another 8 ft section.

The waves are certainly there and are measured in
the process of determining the values of the
s-parameters. That's enough proof of their
existence for me. If you deny their existence,
you are denying that the s-parameter measurement
procedure is valid.

Jim, what happens to the ExB power density in the
equal and opposite fields that cancel?

> 73, Cecil http://www.w5dxp.com

Ah, I can see you didn't take me seriously. But I was dead serious.
It is absolutely not necessary for the source to be dissipating the
reverse wave it sucks up as heat.

A challenge: given a linear system consisting of a source of
impedance Z1, connected to a line (any length you want; any loss you
want) of impedance Z2, and the far end of the line connected to a load
of impedance Z3, or even to a different source of impedance Z3
(possibly different frequency, phase, and/or amplitude from the first
source). Give us one example, even one, that's not accurately
described by source Z1 launching waves into impedance Z2 in the
"forward" direction, plus whatever "reverse" wave is on the line doing
exactly the expected things at the Z2:Z1 boundary. In other words,
viewed from both sides, show us even one instance where the system is
not correctly analyzed with your S11--S12 equations for the Z1--Z2
interface. Show us even one instance where those equations will not
tell you exactly what happens to waves coming into that interface from
either direction, and in fact from both directions at once.

What the source does with the incoming wave is another matter,
independent of the Z1--Z2 interface. Whether it causes increased or
decreased dissipation of heat in the source depends on how the source
is made, and the characteristics (phase, amplitude, frequency, ...) of
the incoming wave.

4691. A good RF ground

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-19 16:55:03 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <58pl6nF2h9fn1U1@mid.individual.net>
Source record: 42589

I want to put up a "long wire" with the feedpoint at one of the back end corners of the garden. I need a good RF ground.

If I got a length of 6 foot wide copper sheet and made out of it a cylinder, say 6 feet in diameter, and then placed that cylinder in an upwards position in the ground, the top level with the surface, would that be a good idea for trying to acheive a decent RF ground? Also, is there anything I could place around the cylinder to better the conduction between the cyinder and the earth around it? Should I drill holes in the cylinder so I can pour water into the cylinder to keep the ground around it moist?

Would I still benefit from some radials in the ground?

My garden's about 33 foot long, 21 foot wide. Ground gets rather rocky and a bit sandyish at about 9 inches or so from the surface.TIA.

>
> 73,
> Gene
> W4SZ

Yes, but he never made it in terms of reference to antennas. By using
the conservative field transition to a non conservative field as a
follow up example the equation now has more meaning than just
mathematics in that it provides a datum for maximum efficiency.
I don't believe anybody evoked Gaussian law to express a situation for
maximum efficiency
of radiation by specifying an array of resonant radiators which also
was never included in Maxwells laws. Science is improved by what is
seen to many as minor steps that apparently everybody was aware of but
did not know how to take advantage of that knoweledge to provide a
fresh data base for the state of the art. The World was aware of
adding the time contribution but no one, no college, no scientist, no
author, just nobody
provided a kernel of knoweledge regarding equilibrium in connection to
efficient electromagnetic radiation. Knoweledge of a relationship is
one thing , puting that knoweledge to use is required for the
advancement otherwise it plays dead for centuries.
In life everybody claims that an invention is nothing but only one
gets off the couch.
When the application is published you and others have the right to
petition the PTO showing prior publication or prior knoweledge with
respect to the state of the art. This ofcourse requires more than just
words such as spouted off from this newsgroup .You really have to walk
the walk and if you don't understand the underpinnings of what I term
a Gaussian antenna or challege it as a sample of nonsense then it is
you that must provide the facts that make it so and this thread shows

your inadequacy to do so. Only one person came forward to
acknoweledged the presence of conclusive mathematical support supplied
by
John Davis and where the rest of this long thread are in denial,
occupied by empty words of denial without proof. Seems like most
threads are reaching the hundred mark on this group because of
collective confusion of what is really tought at teaching institutions
and the effects of time that make these teachings all different.

That might be overkill.. Why not spend the money on a spool of copper
wire and lay radials. For RF purposes, large area of coverage is more
important than low impedance at a particular point. You want to improve
the apparent conductivity of the soil over as much volume as you can.
Think of your grounding system as (partially) a big leaky capacitor to
"the earth".. you want to spread the RF current out over as large an
area as possible, and radials are probably the easiest way to do it.
There's nothing special about how you lay the radials or their length
(they're in dirt, so they're not tuned or resonant.. just wires).

Hi Richard,

Not particularly.

>Also, is there anything I could place
>around the cylinder to better the conduction between the cyinder and the
>earth around it?

You could slit the cylinder lengthwise and lay it on or beneath the
soil.

>Should I drill holes in the cylinder so I can pour water
>into the cylinder to keep the ground around it moist?

This a bromide from the late 20s and 30s. Yes, it would keep the
ground moist, encourage moss, and increase the density of earthworms.

>Would I still benefit from some radials in the ground?

Always, first, and foremost.

>bit sandyish at about 9 inches or so from the surface.TIA.

Lay out a fan of radials as far as you can go. Make it about a dozen
to sixteen. Move on because there is small chance of significant
improvement beyond that.

Hi Art,

He confirmed it was Maxwell's (Heavisides actually) equations. I provided the actual quotes. If you wish, you can consult the same reference we BOTH used: "The Feynman Lectures on Physics," or I can rummage up that material again.

Andre you did indeed open a can of worms!, A vertical antenna is the
most complicated thing in the world that even a newsgroup full of
antenna experts are having difficulty in solving.
It is quite possible that this thread will top a hundred replies
before you arrive at the right question that they can answer.
Cheers and beers

Cecil,

Progress!

All we need now is that you also understand that waves flowing in the SAME direction do NOT interact unless there is an interface or other discontinuity.

All sorts of things can happen at discontinuities. The detailed physical mechanisms and the models are well understood.

Good 60Hs ground doesnt mean its a good RF ground. The casing of an abandoned well gives me about a 4 ohm 60 hz ground but about 25 ohms ground on 20 meters.

The best answer yet! No special tools involved...
The problem encountered using a level is that you first have to learn
to use a level.

I used to work on a high speed laser printer that was on the 33rd.
floor of a building. Some of the adjustments required the use of a
machinists level. Usually the bubble would wander around a bit. On a
windy day it was down right eerie...

Source record: 42605

Many of us miss Bill, W9INN, and have had years of enjoyment from his FB antennas. When I purchased my antenna from Bill in 1977 or 1978 he provided excellent documentation that I have lost.

Did anyone take the time to scan Bill's documents or have they been saved in a library somewhere?

I would like to get the specifications on his 40/80 reactor (his term for a trap) so mine can be rebuilt.

What started out life as a 40/80 dipole from W9INN was modified by me to add extra sets of wires for 10 MHz and 18 MHz and I got lucky the whole mess works FB on 24 MHz as well as 50 MHz. The antenna has been up for 25++ years and still works great.

W9INN you are missed!

>
> - Show quoted text -

No, he insulted every body elses intelligence.Actually your idea
regarding the piece of angle
as a reference guide for the scribe seemed to be the most practicable.
As yet I have not found the tolerance range for a spirit level whether
it be angular or otherwise. As for insults to ones intelligence I get

them all the time from idiots who do not have the knoweledge to even understand the subject let alone give proof of errors stated that they are trying to challenge.
Look around you Jimmy, here we are in the company of antenna experts, lots of them. Simple questions are posed by newbies and each expert writes something different such that an answer is never arrived at. There is not one expert here that can give a single response that can satisfy all posters which really gives meaning to don't just ask one expert, ask a dozen experts and then punt. I often get comments that my statements are not clear
but check out some of the threads that have over 100 or 200 responses, obviously I am not the only one that is not clear in my writings. Just imagine all the insults floating around on things imaginary or things that are virtual or even simple things such a SWR and then some body suggests to a newbie that he throw all his measuring instruments, scribers, micrometers but keep only ,yes only, the spirit level when dealing with the building of antennas ! Maybe it is time to give up my subscription to RADCOM if this is what I have been paying for. Jimmie you are one of many that hang apon my tail with the pretense of being an expert and sooner or later you will look back on this thread wondering how I could have been so dumb to follow the other naysayers when I see so much use of Gaussian antennas being made. Some asked for mathematical proof and when they got it from an indepedent source they are so much in denial that they keep on digging a hole for themselves but cannot come up with anything that faults the mathematics and thus resort to silly talk or flowery language that just shows up as a bunch of weeds. Jimmie give me something of substance we can talk about to separate us from multi posters who seem to be doing their utmost in talking about other things other than antennas and opting for theoretical talk that emboldens those to post likewise in coat tail fashion.
Art.....See you at Dayton, I'll be on the look out

> open circuit.

I've always liked this example. By extension, on a line multiple
quarter wavelengths long, you can disconnect the line at ANY
of the voltage maxima and see exactly the same result as you
describe above. Are those travelling waves really crossing the
voltage maxima? Or are they being reflected? Or are they just
reflected at the maxima that actually occur at a discontinuity?
But there is no discontinuity at the source, so why would they
be reflected there? But if they are reflected at the
non-discontinuity at the source, then they should be reflected
at the non-discontinuities in the line as well. But wait, those
non-discontinuities are virtual opens and shorts, so maybe
they reflect at virtual ones as well. But no, it has been agreed
that reflections only happen at physical discontinuities.

And what if the stub is not a quarter (or multiple) wavelength
long? Then where does the reflection at the source occur?
At the last maximum or minimum along the line? Inside the
generator? It works for any length of line. Somehow the
generator knows exactly what reactance to supply?

It is definitely best to recognize that when the source impedance
is equal to the line impedance, there is no reflection at the
source. And it does not matter if the source impedance is
achieved with a circulator, a resistor, a multiplicity of resistors,
feedback, or what have you; there is no reflection if the
impedance is the same as the line. No discontinuity, no
reflection. A simple rule. Works at a load. Works at a
generator. Works along the line. Always works.

...Keith

Well Gene you have admitted in the past to having an extensive
background in physics, three
educational degrees no less, are you still in denial with respect to
the authenticity of the mathematics provided by Dr Davis? You never
have enunciated a change from your prior comments regarding that
subject.
Also you have pointed out that all is known by you yet you keep
stating that the Gaussian connection with respect to static fields
have no connection academically with radiation but never with any
proof. You and many of the other naysayers can point to an example of
radiation that stems from Gaussian law. Many have even stated that
there is no connection
between Gaussian law of statics and radiation even in the face of
irrifutable mathematics evidence provided. On the other side of the
coin people state it WAS already known in total opposition to other
posts that they have made. Ofcourse every body knew it they all read
it somewhere where the subject was discussed but memories appear to be
to hazy to recall exactly where it was discussed, used or totally
trashed. Now we have moved to Feynman and his series of teachings, did
he have a volume on the subject that was stolen at the outset? Gene
you have been given mathematical backing to what I have stated did you
get all those degrees without studying math? With all those degrees
you have you should be able to understand not only the math supplied
but also give a scientific analysis as to why
conservative fields and non conservative fields can prove or disprove
a continuum between statics and electromagnetism in a legible form
that enphasises your background knoweledge that you claim. Only once

4711. Multi-band dipole question

Newsgroup: rec.radio.amateur.antenna

Hello,

Just joined the group and I have a question about constructing a multi-
band dipole.

I plan to construct a 80/40/20/15 band multi-element dipole using
separate dipole wires for each band,
but a single feedpoint. My question is: how important is the spacing
BETWEEN the
individual band wires. I understand that they can't/shouldn't touch,
but is there any distance
that is optimal? or is just keeping them from touching enough?

Thanks,

Mike

I have used those antennas most of my life. I call mine a
parallel-fan dipole. I usually use 4" spacing for convenience. I use
PVC pipes with holes drilled in them the same diameter of the wire for
spacers.
However, there is a little secret to the parallel-fan. If the spacing
is pretty close to 8 inches apart, then you can setup the 75/80 meter
element and reverse engineer the length to the frequency. THen
substitute the new formula for the 468/f formula and you won't do so
much trimming on the other elements.

The advantage to the 4" spacing is that on 80 & 40 meters, you get a
broader bandwidth.

I really don't know of any better dipole arrangement when there is
room enough for this one.

Can a wave exist without energy? Where does the energy in the
sucked up wave go since it doesn't go into the source.

It was only AFTER the intervention did you aknoweledged the undeniable
truth of what
Dr Davis presented. Before then the debate was about the legitamacy of
adding time to both sides to the Gaussian law on statics. You posted
often in that debate as did all the other experts all in total denial
of the veracity of what I stated. True many of your posts are clounded
with flowery language to emphasis your position but never did a
specific point make it thru to any sort of objective. At any time you
or anybody could have turned around in your thinking and point your
spear in the ground alongside me but none did. Even after the
intervention of Dr Davis only one person followed thru until personal
satisfaction was obtained
regarding the mathematics. I seem to remember an obscure posting that
you made towards
Dr Davis that seemed to have undertones of disagreement but ithe prose
was difficult to understand so there is no personal credit you can
steal for your self, you had posted so many times prior to that time
in dissent. In years to come this thread will be read time and time
again as evidence of the multi pseudo experts who lived on this
newsgroup that argued without any grounds whatso ever about science
and Gaussian antennas and I will cherish that time as the so called
experts are finally exposed for what they are to the amateur radio
fraternity. Ofcourse you could re write all of your posts such that
true scientific data could penetrate the maze place in the way to
prove your position one way or another or even point to the chapter
that you were first to disclose to the world the veracity of what I

had to say but then you can't because it doesn't exist, many have spoken of this proof but none have been able to deliver and neither can you. Richard you are a fraud.

There's no conflict between those two statements. s11(a1) and
s12(a2) indeed *NEVER* encounter an impedance discontinuity
since they originate already flowing *away from* the impedance
discontinuity. Any interference between two coherent collinear
EM waves traveling in the same path is a permanent interaction.

Play your silly word games if you will. Fields cannot cancel unless those fields first exist. Assume E1xB1 joules/sec associated with the first field and E2xB2 joules/sec associated with the second field. The fields cancel. What happens to the E1xB1 joules/sec and the E2xB2 joules/sec? Hint: Their energy components are redistributed in a direction that allows constructive interference. In a transmission line, there is only one other direction available.

> but is there any distance
> that is optimal? or is just keeping them from touching enough?

That's a good question, and here's the answer:

If you fan them apart at a fairly large angle, they don't interact much, so on each band the antenna acts pretty much like the other elements aren't there. But as you decrease the spacing, the interaction increases, with several noticeable consequences. First, the resonant length of each element is affected by all others. Mostly, the long elements affect shorter ones. So tuning the antenna requires adjusting the longest element first, then the next shorter one, and so forth. The lengths you end up with are somewhat different than you would if the elements were independent. Second, the antenna becomes more narrowbanded on each band, except perhaps the lowest frequency band which uses the longest element. Third, the feedpoint impedance at resonant frequencies will be somewhat different than it would for an independent dipole. All these effects increase as the spacing between elements decreases. I haven't done a study, but believe that coupling will alter the patterns of the higher frequency antennas somewhat when spacing is close. Efficiency should be just fine for any spacing, though, so you'll be radiating essentially all power you feed it.

Having 15 and 40 meter elements in the same antenna might make things more difficult, because on 15 meters, the 40 meter element will be near resonance and will get a fair amount of the power. It'll still radiate, but you might find an unusual feedpoint impedance. You might consider using the 40 meter element for both 40 and 15 -- you can probably tune it to be reasonably close to resonance on both bands. On 15 you'll get a cloverleaf pattern, but if you bend the two wires each 30 degrees in the same direction to make a vee with 120 degree included angle, you'll get a fairly narrow bidirectional pattern.

Sorry Jim, the s11(a1) wave and s12(a2) wave are *NEVER*
incident upon an impedance discontinuity yet they cancel.
How do two waves cancel without interacting?

You are getting close to the truth. Yes, the forward and reverse
travelling waves are not necessarily moving energy. The Bird
wattmeter, despite its name, is computing a number with the
dimension of watts, but which does not necessarily represent
energy flowing (it represents flowing energy when the indicated
value is 0 in one direction or the other).

This will probably (I understate) be hard to accept but is the
only reasonable conclusion after examining a large number
of experiments and trying to rationalize the answer
to "Where does the energy in the reflected wave go?" Once
it becomes clear that there is no good answer to that
question, the only possible conclusion is that the question
is invalid and the roots of its invalidity lie in the assumption
of energy in the reflected wave.

> discontinuity.

Please stop implying things that I have never said. When I
asserted that reflections only happen at a physical impedance
discontinuity, that implies that interaction can only happen
at a physical impedance discontinuity. It is impossible to
get two coherent waves flowing in the same direction except
at a physical impedance discontinuity.

Assume b1 = s11(a1) + a12(s2) = 0

What I have said is that s11(a1) and s12(a2) are wave components
that cancel without ever being incident upon an impedance discontinuity.
Those two wave components originate at the impedance discontinuity
flowing *AWAY FROM* the impedance discontinuity. They are canceled
in a delta-t, i.e. a very short time. Those two waves are the result
of interaction at the impedance discontinuity but neither of them
ever interacted with the impedance discontinuity because they
originated at the impedance discontinuity.

Wow! Thanks for so many replies so quickly. I think I will go with a
"fan" design rather than parallel.
Another question though. What balun should I use? 1:1? 2:1? 4:1?
How do I know which?
Or can I just do the "coil the coax" thing...?

Thanks

There is no impedance discontinuity - therefore no
reflections.

> But there is no discontinuity at the source, ...

You are still making the same mistake as you have from
the beginning. There is a discontinuity at the source.
In your example, it is called the load-line. The load-
line in the previous example is source voltage divided
by zero, i.e. infinity. That's what the reflected wave
sees.

> It is definitely best to recognize that when the source impedance

Side issue - you can get by using the 40m dipole for 15m.
40m dipoles and 15m dipoles interfere with each other
on 15m.

Please clarify for us the distinction between canceled fields, and
fields which don't exist.

There is no energy traveling in the direction of fields that cancel;
E1xB1 and E2xB2 in this example.

> Assume E1xB1
> joules/sec associated with the first field and E2xB2
> joules/sec associated with the second field. The fields
> cancel. What happens to the E1xB1 joules/sec and the
> E2xB2 joules/sec?

Since the fields cancel, and energy does not travel in the company of
nonexistent fields, there is no energy here with which to concern
ourselves.

> Hint: Their energy components are
> redistributed in a direction that allows constructive
> interference. In a transmission line, there is only
> one other direction available.

Producing a result which can only occur when there is no energy
traveling in the direction of E1xB1 and E2xB2.

How in the world is EM traveling waves existing without
energy getting close to the truth? Seems it is getting
closer to fantasy than anything else.

> The Bird
> wattmeter, despite its name, is computing a number with the

> energy flowing (it represents flowing energy when the indicated
> value is 0 in one direction or the other).

If the Bird is properly used, it indicates joules flowing
past a point in one second in the environment for which it
is calibrated. If EM energy waves ever stop flowing, they
cease to be EM waves. The boundary conditions for EM waves
will not permit them to travel at any other speed than
d(VF) nor exist devoid of energy.

False, false, and false. *Every* EM wave is associated with ExB
joules/sec. The energy supporting a reflected EM wave is either
reflected or transmitted or dissipated. Those EM waves do not
care a whit if you never figure them out.

Ah, thank you. Then it follows directly from that, that when you
wrote,
> A Bird wattmeter reads 100 watts forward and 100w reflected. The
> current in the source is zero. The source is not only not sourcing any
> forward power, it is also not sinking any reflected power.
you were not disallowing the fact that the source, which is matched to
the line, sucks up the entire reverse wave from the line. I'm happy
to see we agree on that little point after all.

Fallacies of the, "if the source absorbs the reverse wave, it must be
dissipated as heat," school: Start with a source which is a voltage
generator, 141.4Vrms sinewave, in series with a 50 ohm resistor.
Connect it to a 50 ohm load, and you have 100 watts dissipated inside
the source and 100 watts dissipated in the load. Put a 50 ohm
lossless line between the source and the load. We now have a
70.71Vrms wave from the source to the load, and no reflected. Assume
the line is 1/4 wave long; replace the load with a short. A moment
later, steady state is reached and the dissipation in the source's 50
ohm resistor dropped from 100W to 0W. We may be tempted to say that
source did not absorb the return wave and is no longer supplying the
forward wave. But that requires complete reflection of the return
wave at the interface between the source and the line. Ah, but there
is an infinite set of conditions under which the same should be
true. What if we make the line 1/2 wave long, still shorted at the
far end? In steady state, the source is still apparently delivering
no power to the line, but now, instead of it dissipating NO power,
it's suddenly dissipating 400 watts! In the line, though, we still
see 100 watts of forward power, and 100 watts of reverse power.

Ooops. The "if the source absorbs the reverse wave, it must be dissipated as heat" school ... better go back to school. Or to the lab. Or SOMEwhere else, till they get it figured out. It didn't hold water when Dr. Slick (remember him?) tried to push it on us, and it doesn't hold water now.

More fun: the guts of my source are now a 282.8V source and the 50 ohm resistor, feeding a fairly long piece of 50 ohm transmission line to the front panel connector. The line has 6.02dB loss. Now back to the original situation with 1/4 wave of 50 ohm line, shorted at the far end, connected to the generator's output connector. NOW are you going to say that the reverse wave on the 1/4 wave line stops when it gets back to the generator? What if I put even a couple inches of line between the guts of the source and the front panel connector, does the reverse wave on the external line stop when it gets to the front panel connector?

I repeat: [In the case of a line connected to a source, with the impedance of the two matched--not conjugate] It's obvious that the source is sourcing the forward voltage wave, and it's sucking up the entire reverse voltage wave from the line.

What happens to that reverse voltage wave inside the source depends on what's in the guts of the source.

From the lab,

Bunsen

4731. Flexible/Durable FM Antenna for Jeep?

Newsgroup: rec.radio.amateur.antenna

I have destroyed several stock antennae on my Jeep during trail rides when they get snagged by brush and easily bent. I went to a short (maybe 1' long)flexible type, but my reception absolutely sucks now. Can anyone suggest a car-type antenna that will have good reception, but can take a hit? I'd prefer to use it in the original place as I already have a hole in the body, but one of the amplified -inside-the-winshield type might be an option if it is worth anything.

4732. Independence of waves

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-19 21:42:43 UTC
From: Owen Duffy <none@no.where>
Message-ID: <Xns99184E734F2D7nonenowhere@61.9.191.5>
Source record: 42480

There has been much discussion about wave cancellation, anihalation, interaction etc. The discussion was initially about waves confined to a transmission line (but would apply also to a waveguide in a sense) and then progressed to radiation in free space.

Let me initially explore the case of radiation in free space. I am talking about radio waves and the radiation far field.

If we have two widely separated antennas radiating coherent radio waves don't they each radiate waves that travel independently through space. (I have specified wide separation so as to make the effect of one antenna on the other insignificant.

If we were to place a receiving antenna at a point in space to couple energy from the waves, the amount of energy available from the antenna is the superposition of the response of the antenna to the wave from each source. This is quite different to saying that the electric field (or the magnetic field) at that point is the superposition of the field resulting from each antenna as is demonstrated by considering the response of another recieving antenna with different directivity (relative to the two sources) to the first receiving antenna.

A practical example of this is that an omni directional receiving antenna may be located at a point where a direct wave and a reflected wave result in very low received power at the antenna, whereas a directional antenna that favours one or other of the waves will result in higher received power. This indicates that both waves are independent and available to the receiving antenna, the waves do not cancel in space, but rather the superposition occurs in the antenna.

Though we frequently visualise nodes and antinodes in space, or talk of nulls in space (eg have you ever noticed that when you stop a car at traffic lights, you are smack in the middle of a null), whereas it seems to me that the realisation of a null involves the response of the receiving antenna.

This explanation IMHO is more consistent with the way antennas behave than the concept that waves superpose in space, it allows waves to radiate outwards from a source, passing through each other without affecting each other. Whilst we routinely look at plots of the directivity of an antenna, and assume that the plotted directivity is merely a function of polar angle, we overlook that the plotted pattern assumes an isotropic probe at a distance very large compared to the dimensions of the antenna (array). Tracing the position of a pattern minimum in towards the array may well yield a curved path rather than a straight line, and a curved path is inconsistent with waves anihalating

each other or redistributing energy near the antenna and radiating outwards in true radial direction from some virtual antenna centre.

So, it seems to me that coherent waves from separated sources travel independently, and the response of the probe used to observe the waves is the superposition of the probe's response to each wave. (A further complication is that the probe (a receiving antenna) will "re-radiate" energy based on its (net) response to the incoming waves.)

Now, considering transmission lines, do the same principles apply?

A significant difference with uniform TEM transmission lines is that waves are constrained to travel in only two different directions.

Considering the steady state:

If at some point two or more coherent waves travelling a one direction, those waves will undergo the same phase change and attenuation with distance as each other and they must continue in the same direction (relative to the line), and the combined response in some circuit element on which they are incident where superposition is valid (eg a circuit node) will always be as if the two waves had been superposed... but the response is not due to wave superposition but superposition of the responses of the circuit element to the waves. It is however convenient, if not strictly correct to think of the waves as having superposed.

That convenience extends to ignoring independent coherent waves that would net to a zero response. For example, if we were to consider a single stub matching scheme, though one there might consider that multiple reflected waves arrive at the source, if they net to zero response, then it is convenient to regard that in the steady state there are no reflected waves, the source response is as if there were no reflected waves. An alternative view of that configuration is that superposition in the circuit node that joins the stub, the line to the load and the line to the source results in conditions at that end of the source line that do not require a reflected wave to satisfy boundary conditions at that point, and there really is no reflected wave.

Steady state analysis is sufficiently accurate and appropriate to analysis of many scenarios, and the convenience extends to simplified mathematics. It seems that the loose superposition of waves is part of that convenience, but it is important to remember the underlying principles and to consciously assess the validity of model approximations.

Comments?

And are put into a load.

As waves are completely independant, then they never interact. A load
is required to reveal the cancellation. No load, and any issue of
cancelling fields is strictly limited to what goes on between the
ears.

Hi Art,

Well, in fact it was Dr. Davis (who came into the discussion rather late) who had to agree in the end with those who presented the simple connection between Maxwell (actually Heaviside) with his time variant magnetic fields and Gauss with his time invariant magnetic fields. Every antenna modeler on the market employs the time variant magnetic fields' math described by Maxwell (actually Heaviside).

Maxwell is about dynamics, which means time variant; and Gauss is about statics, which means time invariant (or constant, never changing). If you inject a "cessation of time" you are already in the dynamics side of magnetics = Maxwell.

Are you declining the invitation to review Feynman? He is pretty accessible, not much math - except for what really counts.

If nobody is there to hear it, does a tree that falls in the middle of the forest (or anywhere else) make a noise? If there's a field and nobody is there to measure it, is it there? If there's a summation to zero and there's nobody there to verify that the summation really occured, did it occur? Wheeee! Where will this take us next? Beaker is soooo excited by the possibilities.

You won't need much of an impedance transformation, so a 1:1 "current" balun (common mode choke) is appropriate. A coil of coax makes a broadly resonant circuit for currents on the outside, so acts as a current balun over a fairly wide range of frequencies. My experiments show a reasonable impedance over about a 3:1 or so frequency range. To be effective over a wider bandwidth, you'll need a couple of different sized coils, or a balun using ferrite, which is inherently broad banded.

But the load line is the same for the generator equipped
with a circulator so it too must reflect the wave. If this is
the case, what heats the circulator load resistor?

I notice you skipped the tougher questions related to a
transmission line that is 3/8 wavelength long? Is there a
zero to divide by in this case? Apply analysis equally
to Experiment A and B.

That'll get you on those three bands and, as I mentioned, you can probably get a reasonable impedance on 15 as well by fiddling the 40 meter antenna a bit. It won't be quite resonant on 40, but probably close enough so your rig won't shut down.

Old diversionary trick - doesn't work. We do NOT agree on "that
little point". Agreeing on that little point requires negative
energy which doesn't exist. The reflected energy is 100% re-
reflected. Nothing is coming out of the source and nothing
is going into the source.

ABSOLUTELY NOT!!! The load line for a circulator equipped
generator is *ALWAYS* 50 ohms (for a 50 ohm generator).
The generator *always* sees 50 ohms as a load. How could
the load-line possibly be anything else besides 50 ohms?

Hi Tom,

And how are you going to sum it without a load?

>and there's nobody there to verify that the summation really
>occured, did it occur?

Nobody, I presume to mean no body of a load. No load hence no
combination, hence no interference.

Fairly simple stuff, but mystics here still demand that energy
disappears in these situations to be "shuffled" around like balance
ledgers done by Arthur Andersen for billing electricity to California.
Some things never change.

If you (a body) happen to be there, then yes you "might" detect a
null, a peak, or any combination in between. You (the body) are the
load. Even that is a stretch of the imagination, but your
Doppelganger can no doubt spread it out. I suppose if the fields were
viciously strong you might feel a prickle of heat (or cool, some RF
waves lend that perception). Otherwise the waves simply go on their
way without any notice of the other, and certainly to no literal
notice at all. Why would it be otherwise?

Well this is the point you lock up on and it is one of the root
causes of all subsequent errors. I suspect your refusal to
accept the common knowledge that the output impedance
of the generator can be well known, that this controls the
amount of reflection at the generator and that superposition
works is the realization that this will conflict with "energy in
the waves". I encountered the same dilemma when first
dealing with these questions, but came to the answer that
works.

> Real world conditions are not as simple-minded as you say.

But, of course, your proof of re-reflections was your apriori
knowledge of the interior of the generator. I present you with
two 50 Ohm generators; one constructed with a circulator and
one constructed with a 50 Ohm resistor. How do you tell which
is which? The line conditions will be the same, so you can't.
Do you really want a theory of reflections that is dependent on
knowing the internals of the generator?

> > It would be more precise to say "The source sources 100 watts

Yes indeed. All line conditions are exactly the same. The same
energy is stored. The output impedance is the same. Modulation
has exactly the same effects. The reflected modulated signal is not
re-reflected at the source for either case. They are
indistinguishable unless you dissassemble the generator.

You can not possible be arguing that P is not equal to V times I,
can you?

And are you disputing that if V or I is at all times 0, there must be
no energy flowing.
If so, back to grade 11 science please.

Well it is pretty clear to me that if the net current is always 0,
then
no current is ever flowing and the power must be zero.

It seems to be a bit of a common fallacy to assign meaning to the
intermediate currents computed for the superposition solution to
a problem. Connect two equivalent batteries in parallel. The only
sensible answer is that no current is flowing since the voltages
are the same. (In another post you seem to accept this), though
if you use superposition to solve the problem, you get a very large
current flowing in one direction and an equally large current flowing
in the other. Only the resultant current is in any sense real. Same
for those waves on a transmission line. Just superposition. Just a
convenience to help reach the final solution. Don't over extend
and assign them meaning (or energy). In the end it will cause
deep conceptual difficulties.

But conditions in the sources are exactly opposite. One
is sourcing and sinking power. The other is completely
powerless.

> Please apply this calculation to Experiment A and check
> your result. No difference. Ooooppps.

Ooooppps means you obviously made a mistake. The conditions
are opposite not alike.

> And if you did the same test with Experiment B you would get the

Obviously not since source B is at room temperature.

> No different for B.

Source A is dissipating 200 watts. Source B is dissipating
zero watts. How is that not different?

> Well this is the point you lock up on and it is one of the root
> causes of all subsequent errors. I suspect your refusal to

The example proves this to be a wrong-headed concept.

> I present you with
> two 50 Ohm generators; one constructed with a circulator and
> one constructed with a 50 Ohm resistor. How do you tell which
> is which?

The one with the rapidly rising temperature is the one with
the circulator. The one that remains at room temperature
is your ten cent resistor version.

> Yes indeed. All line conditions are exactly the same.

But the source conditions are radically different. One
source is sourcing 100 watts and sinking 100 watts. The
other source is sourcing 0 watts and sinking 0 watts.

> You can not possible be arguing that P is not equal to V times I,
> can you?

Pfor - Pref = 0 where those Ps are Poynting vectors.
Pfor is not zero. Pref is not zero. Pnet is zero
only because of a directional convention.

> And are you disputing that if V or I is at all times 0, there must be
> no energy flowing.

Make that at all times AND AT ALL PLACES and I will agree.
If V is zero it only means that all the energy has migrated
into the magnetic field and indeed, when V is zero, I is
at a maximum.

> Well it is pretty clear to me that if the net current is always 0,
> then no current is ever flowing and the power must be zero.

True if the net current everywhere is zero. Not true if the
current is only zero at a point. Current on each side of
a zero current point is prima facie evidence of energy flow
in both directions.

You are lying again. You never convinced the Doctor in any sort of
corrective way, only one person stated agreement with his summation of
mathematics No body in this group has brought forward prior knowledge
or agreement between conservative and not conservative fields by use
of the Gaussian method. Oh how quickly people forget their anger of
the idea of connecting static with non static situations. My goodness
how soon you forget the slander projected because of this supposedly
silly idea. As far as going with you to review Feynman forget it. If
you can find proof of anything relevent fine it would give a good
starting point as to why antenna engineers declined to pursue the
discovery. Frankly I am getting close to the position that most do not
understand antennas, what I am proposing and just want to prove their
masculinity by way of slander, this ofcourse does not apply to you.
I believe this thread will make a wonderfull story in the future as to
how rank amateurs tried to stop science from advancing. The material
is here both funny and sad which will come into focus when the patent
is awarded and interest picks up. True I have provoked people to

verbalise their thoughts but for good reason I want to show all what you really are in the near future.Sooner or later this all will be discussed in all educational institutions and the next generation can move forward without hindrence from the agrivation of a bunch of old men.

I believe there's at least one basic fallacy in your development.

The problem is that a directional antenna can't be made to take up zero space. Let's consider a situation where we can have complete cancellation of waves from two sources. There surely are many others, but let's look at this one for starters.

Consider two identical vertical omnidirectional antennas radiating equal, out of phase fields. There will be a plane of zero field passing directly between them, where their fields sum to zero. My challenge is this: Devise a directional antenna which lies entirely in this plane and which has a response that's different for the two antennas. That is, an antenna which has a stronger response to the field from one antenna than the other. I maintain that you can't do it. Your directional antenna must extend beyond the plane, where the cancellation isn't complete. And it's there where it gets its signal to deliver to the load, and where it can distinguish between the two fields.

Also, any antenna placed in a field in a way that it delivers a detectable signal to a load alters the field. That's a second potential problem with your development. However, I believe that the first problem is enough to invalidate it. If the initial analysis of fields in space is invalid, and I believe it is, then the extension to transmission lines is based on a false premise and is questionable.

I maintain that there is actually zero field at a point of superposition of multiple waves which sum to zero, and that no device or detector can be devised which, looking only at that point, can tell that the zero field is a result of multiple waves. This is a very important and fundamental point, and I'm glad you brought it up. If you or anyone can devise an example where a directional antenna can be placed entirely in a region of zero field and yet detect that the field is made up of multiple fields, please present it.

I am, of course, assuming that everything in this discussion takes place in a linear medium.

Well, sort of. Waves superpose everywhere, including presumably, the
space that an antenna might happen to occupy. But an antenna that
approaches a wavelength in physical length will not see a uniform
pattern along its length. The net effect will certainly be a function
of the orientation of the antenna.

It is certainly true that a probe can perturb the nature of the
environment it is investigating. But it is not accurate to describe
the probe as determining the nature of that environment. If it is
effective, it will simply observe and report nature.

Every mapping of an antenna's radiation lobe characteristics presumes
this. We call them receivers.

>> No load, and any issue of

Contrary to the implication of Tom's tree falling unheard in the
forest, no I am not suggesting that. If one plants a load at a
distance and ignores it; then, yes, interference occurs. Remove the
load, and you remove interference.

1. Interference follows the load.

2. A load will also perturb the fields by the degree it couples to
the fields, and create a new interference solution.

Roy, the type of probe I was considering does take up space, and I understand your point that therein lies a possible / likely explanation for its behaviour.

I was thinking along the lines of the superposition occuring within the directional antenna where segment currents would each be dependent on the field from each of the sources (and to some extent field from other segments of itself), and the antenna was where the superposition mainly occurred. But you are correct that the antenna is of non zero size, and the segments that I refer to are not all located at a point where the field strength from each source is equal and opposite.

...

> I maintain that there is actually zero field at a point of

I understand the second point.

Extended to transmission lines, I think it means that although we can make an observation at a single point of V and I, and knowing Zo we can state whether there are standing waves or not, we cannot tell if that is the result of more than two travelling waves (unless you take the view that there is only one wave travelling in each direction, the resultant of interactions at the ends of the line).

I will think some more about the "actual zero field", but that cannot suggest that one wave modified the other, they must both pass beyond that point, each unchanged, mustn't they? If that is so, the waves must be independent, but the resultant at a point is something separate to each of the components and doesn't of itself alter the propagation of either wave.

Source record: 42501

I use a fan type dipole. The wires are 66' 33' and 16' each side so double that for total length. (befor I tuned them but thats close) with an air wound choke at the feed point.
Fan is not exactly right for my antenna ...here is what I did...

I used pvc as a spacer between each wire, the first spacer is 12 inches from the feed point (I wanted to get the wires apart from each other as close to the feed point as possible to minimise interaction between them)

They are separated 12 inches apart over the whole length and hang under each other, the longest being on top.
The top wire (the 66') is the one that has rope connected to it (via insulator) to tie the ends of the dipole to whatever. in my case, It is an inverted V so I used 2 20' poles to anchor the ends of the dipole to.

Since the ends of the 33 and the 16 footer were just hanging from the pvc spacers attached to the 66 footer, I placed a weight at the ends of them to keep it all from twisting up in high winds.

I also ran a line from the ends of the 33 footer down to my poles (a few feet below where the ends of the 66 is tied off, for the same reason. (I find that weed eater string holds up really well for this and it is cheap)

I can use it on all bands from 10 to 80 meters and even right around 1.8 mhz on 160 with a cheap mfj tuner. (not sure why it will work at 1.8 mhz, I never worked out the math)

I get great signal reports with it on my ts-440s (bare bone at 100 watts) and as a general rule, if I can hear them, I can work them.

Of course we can turn that around by building the generator for
Experiment B in the Norton style instead of the Thevenin style.
Then it will dissipate 4 times the power it would when terminated
with 50 Ohms.

Or how about the variant that will dissipate exactly the same
as the circulator without having one. Its dissipation always
numerically rises by the same amount as the "reflected power".
You should work on this generator since it would really help
convince people that the reflected power is dissipated in the
generator.
(Hint: There are two ways to build it and you need a current
source, a voltage source and two resistors.)

> > Please apply this calculation to Experiment A and check
> > your result. No difference. Ooooppps.
>
> Ooooppps means you obviously made a mistake. The conditions

In your characteristic style, you have removed the description of
what is being compared so the reader can not refer back and notice
that you are just contradicting. Oh well.

> > And if you did the same test with Experiment B you would get the
> > same result.
>
> Obviously not since source B is at room temperature.

Minor changes to the generator for B can give you a very hot one
or one that is exactly the same temperature as the one with
the circulator. Your simple contradiction is a an exceedingly weak

argument.

> > No different for B.
>
> Source A is dissipating 200 watts. Source B is dissipating
> zero watts. How is that not different?

The conditions on the lines are indistinguishable and yet you
claim one is reflecting and one is not. How did the line know
whether it should reflect or not? Or is the wave that knows?

> > Well this is the point you lock up on and it is one of the root

>
> The example proves this to be a wrong-headed concept.

You really should crack a basic text book, although you are
in kind of deep now to back track so that path does carry
high risk. You could also google or try the simulation. All
will support the statement I made above.

> > I present you with
> > two 50 Ohm generators; one constructed with a circulator and

> is your ten cent resistor version.

But if we use a Norton style, which one gets hotter?
Or the third style (have you worked out how to build it yet?),
which will dissipate exactly the same as the circulator.

> > Yes indeed. All line conditions are exactly the same.
>
> But the source conditions are radically different. One

> > can you?
>
> Pfor - Pref = 0 where those Ps are Poynting vectors.
> Pfor is not zero. Pref is not zero. Pnet is zero
> only because of a directional convention.

Actually Pnet is zero because of basic circuit theory and the
universally accepted understanding that P = VI.

> > And are you disputing that if V or I is at all times 0, there must be
> > no energy flowing.
>
> Make that at all times AND AT ALL PLACES and I will agree.
> If V is zero it only means that all the energy has migrated
> into the magnetic field and indeed, when V is zero, I is
> at a maximum.

In circuits, we measure the power at a particular place.
I certainly want my power company to do this. If the voltage
or current is 0 at a particular place in the circuit then no
energy is flowing at that place in the circuit. If you are disputing
this, I contend that you do not accept that P = VI.

> > Well it is pretty clear to me that if the net current is always 0,
> > then no current is ever flowing and the power must be zero.

> True if the net current everywhere is zero. Not true if the
> current is only zero at a point. Current on each side of
> a zero current point is prima facie evidence of energy flow
> in both directions.

Inventive. But it doesn't fly. P = VI or it doesn't.

In fact what happens is the energy flows towards the voltage
and current nulls from both sides at the same time, then it flows
away. But it never crosses. Of course, the above statement
applies to sinusoidal excitation. The story is a bit different for
pulse and step. If the line is excited by a step function, for
example, after the reflection makes it back the generator, the
current is zero everywhere, though the 'Bird Watts' are still
'flowing' (but it does take a DC coupled directional wattmeter
to observe this).

Wes, I agree, that is entirely practical. As far as bubble technology goes, senstivity easily exceeds that, IIRC the plate bubble sensitivity on theodolites is commonly around 20" (seconds) per 2mm run. By reversing such a bubble and splitting the difference, it should be possible to achieve an error well under 0.1mm/m slope.

Realistically, most bubbles for engineering workshop use would be more accurate than the drilling process, so they are a quite adequate means of registering the work.

I have used them with success, but prefer an indicator that I can see clearly while tightening the vice.

Hi Art,

Feynman merely confirmed the math of 70 years of antenna design before him. Nothing has altered since 1963, dynamic magnetic fields are still defined by Maxwell's (Heaviside's) equations, and static magnetic fields are still defined by Gauss' equations. Any discussion of the "cessation of time" immediately casts all work into Maxwell's (Heaviside's) math.

Nothing had to be invented because Maxwell (Heaviside) had done the basic math long before antennas were ever discovered. In fact, about 190 years ago Augustin-Jean Fresnel beat them all to the punch without a flicker of electricity or magnetism ever entering the picture.

Antenna engineers have been using Fresnel math too. Amateur radio operators respond to it every time they complain of picket-fencing on 2M. That math is contained in EVERY antenna modeler that offers radiation characteristics.

Cecil,

I am familiar with all sorts of weird and wonderful things that happen on surfaces and really close to interfaces and discontinuities. However, classical transmission line theory does not deal with any of those things. I don't believe any of the recent discussions on RRAA have dealt with these close-in effects either.

Where are the equations that describe this "delta-t" stuff that you keep bringing up? How long is delta-t? What justification do you have for saying that the waves start out from some point and then shortly thereafter decide to cancel? Do they annihilate each other suddenly or is the interaction gradual from time zero up to delta-t? Do you have any references for this behavior? I scanned the Melles Griot tutorial info and the FSU website, but I couldn't find anything about delta-t.

Inquiring minds want to know.

I think you've put your finger right on Cecil's conceptual problem. When we solve the battery example by superposition, we get the right answer, zero current. But now let's put a resistor between the two batteries and repeat the solution. When we "turn off" the left hand battery, we have a lot of power being dissipated in that resistor. Using Cecil's view, we would assign this to be the power associated with the current flowing to the left. Then we "turn on" the left hand battery and "turn off" the right hand battery. Again we have a lot of power being dissipated. This would be the power associated with the current flowing to the right. The problem comes in having to somehow manipulate these powers to get zero, which is what we actually see. The mistake, as you continually point out, is attributing a power to each current -- or each wave -- in the first place.

Yes, each element is seeing a different field from the other. Those induce different currents in the elements. The sum of those is what ultimately gives you the output from the antenna. If the two elements both were at a point of complete wave cancellation, both would produce zero.

> . . .

> Extended to transmission lines, I think it means that although we can

> state whether there are standing waves or not, we cannot tell if that is
> the result of more than two travelling waves (unless you take the view
> that there is only one wave travelling in each direction, the resultant
> of interactions at the ends of the line).

Hm, let's think about this a little. In my free space example, we had two radiators whose fields went through the same point, and those two radiators were equal in magnitude and out of phase. The sum of the two E fields was zero and the sum of the H fields was zero, so there was no field at all where they crossed.

But now let's look at a transmission line with waves created by reflections from a single source. I believe that there is no point along the line where both the E and H fields are zero, or where both the current and the voltage are zero. (Please correct me if I'm wrong about this.) That's a different situation from the free space, two-radiator situation I proposed. So in a transmission line, we can find a point of zero voltage (a "virtual short"), say, but discover that there's current there. There will be an H field but no E field. And conversely for a "virtual open". So there is a difference between those points and a point of no field at all. And there is energy in the E or H field. (This also occurs in free space where a wave interferes with its reflection or when waves traveling in opposite directions cross.) Now, if you could feed two equal canceling waves into a transmission line, going in the same direction, then you would have truly zero E and H fields, and zero voltage and current, like the plane bisecting the two free space antennas. You couldn't tell the difference between that and no waves at all. But as Keith recently pointed out, superposition of two parallel equal voltage batteries would show large currents in both directions. But they would sum to zero, which is what we observe. And as long as the batteries remain connected, we can never detect those supposed currents. The two-wave scenario I described is in the same category, I believe.

We can readily concede that there is no field, voltage, current, or energy beyond the point at which the two canceling waves meet, without having to invoke any interaction or seeing any violation of energy conservation. Show me the whole circuit which produces this overlaying of canceling waves, and I'll show you where every erg of energy from your source(s) has gone. None of it will be beyond that canceling point.

> I will think some more about the "actual zero field", but that cannot

Hi Owen,

I've seen it written, by a well-respected expert on antennas, that electromagnetic fields may be viewed in either of two different ways. Are there more than two, other than minor variations on the theme? I'm not sure. The two I know from that author are that (1) fields are real physical entities, and (2) that fields are merely mathematical abstractions to help explain our observations: in the case of electromagnetic fields, that acceleration of a electron results in sympathetic motion of free electrons throughout the universe. It seems to me that in either of those cases, the result of fields from multiple sources, in a linear medium, is always the sum of the fields from each of the sources independently. That is practically the definition of linearity, is it not? It does not depend on us putting something there to detect the field, or to test if the mathematical model is correct. Certainly if we were watching waves in water, we could see lines along which there was cancellation, where the water would not be moving. But even if the fields are merely a mathematical abstraction, then I still know where they sum to zero. The utility of a mathematical abstraction to practical folk, of course, is that it can accurately predict the behaviour in the physical world. So if fields are just an abstraction, I can still use them to predict where I can place a wire that's in the sphere of influence of two or more radiating sources, and have the electrons in that wire unaffected by the sources (because those theoretical fields canceled there). On the other hand, if my field theory is describing something physical, if fields are entities apart from (but inexorably linked to) the motion of electrons, then it seems that whether we are able to observe those fields directly or not, their cancellation is real. That does assume that we've correctly deduced the nature of those fields, I suppose, so that our model does say what's going on in that physical medium we can only probe with our free electrons.

Cheers,
Tom

Such diversions - almost everyone is running a threaded newsreader.
All one has to do is click on the previous posting. Not trimming
postings is a violation of usenet guidelines. My pet peeve is
when someone repeats ten pages of postings and adds one line,
like "Right on".

> Minor changes to the generator for B can give you a very hot one
> or one that is exactly the same temperature as the one with
> the circulator.

You've been hammering people with the source of your choice
for days but choose to abandon it as soon as someone points out
a logical problem with it.

> The conditions on the lines are indistinguishable and yet you
> claim one is reflecting and one is not. How did the line know
> whether it should reflect or not? Or is the wave that knows?

One wave encounters a 50 ohm resistor and is dissipated.
The other wave encounters an infinite impedance and is
100% re-reflected - all in accordance with the wave
reflection model.

> Actually Pnet is zero because of basic circuit theory and the
> universally accepted understanding that P = VI.

Circuit theory completely falls apart with distributed
network problems. The currents at two points in the
closed loop are often flowing in opposite directions.

> In circuits, we measure the power at a particular place.
> I certainly want my power company to do this. If the voltage
> or current is 0 at a particular place in the circuit then no
> energy is flowing at that place in the circuit. If you are disputing
> this, I contend that you do not accept that P = VI.

Plenty of energy is flowing - two equal magnitudes
in opposite directions equals zero net energy.

Correction to your P = VI based on DC, not AC/RF:

Net P = V*I*cos(theta) = Pfor - Pref

Forget V and I being 0. cos(theta) is always 0 for a
standing wave. There is ZERO net power anywhere in a
standing wave. (It's a lot like my bank account.)

> Inventive. But it doesn't fly. P = VI or it doesn't.

Forward waves and reflected waves are completely independent
of each other and do NOT interact. Their powers do NOT
superpose. There is nothing but joules moving at the
speed of light in a transmission line. There's no net
energy but your zero energy assertions are just illusions.
EM waves are incompatible with zero energy.

Throughout my time at the USAF technical school, I was frustrated by the hand-waving of the instructors when the topic was electromagnetic fields (and many other topics, for that matter). It was obvious that they really had a very poor grasp of the subject(s). So on the very first day of my first college semester of fields, I asked the professor, "What is an electromagnetic field?" His response: "Electromagnetic fields are mathematical models we use to help us understand phenomena we observe." The professor was Carl T.A. Johnk. I have his textbook _Engineering Electromagnetic Fields and Waves_, which was in draft manuscript form at the time I took the course. The first sentence in section 1-1 on page 1 is "A field is taken to mean a mathematical function of space and time."

Gene Fuller wrote:
> Where are the equations that describe this "delta-t" stuff that you keep
> bringing up?

delta-t is a mathematical term, Gene, related in the limit
to the differential dt. If you have to ask, I'm sure you
wouldn't understand the explanation.

Given the following experiment with two signal generators
equipped with circulators and load resistors - the generators
are phased-locked to ensure coherency:

```
100W 50W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL1 SGCL2
```

Here's the setup for determining s11 and s21 with
SGCL2 turned off.

```
100W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm load
SGCL1
```

Here are the results:

```
a1---->|
|---->s21(a1)
s11(a1)<----|
```

THE EM WAVE, s11(a1), EXISTS, IS MEASURABLE, AND IS ALIVE
AND WELL.

Here's the setup for determining s12 and s22 with
SGCL1 turned off.

```
50W
50 ohm load---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL2
```

Here are the results:

```
|---->s22(a2)
s12(a2)<----|
|<----a2
```

THE EM WAVE, s12(a2), EXISTS, IS MEASURABLE, AND IS ALIVE
AND WELL.

Now power off both signal generators and power them up
simultaneously. Let t=0 be the time when s11(a1) and
s12(a2) first exist. Superpose s11(a1) and s12(a2). How
long does it take to achieve b1 = s11(a1) + s12(a2) = 0?
I estimate that time to be delta-t which becomes dt
in the differential equation limit.

The principle of superposition allows us to observe that
s11(a1) and a12(a2) actually existed before they were
canceled.

Your conceptual problem is obviously that you don't
understand the difference between a DC circuit problem
and an RF distributed network problem.

Can you get DC current to flow in opposite directions
around a closed loop? Can you get RF current to flow
in opposite directions around a closed loop.

Please get real.

I made an error in my last reply and have canceled that reply.

delta-t is a mathematical term, Gene, related in the limit
to the differential dt. If you have to ask, I'm sure you
wouldn't understand the explanation.

Given the following experiment with two signal generators
equipped with circulators and load resistors - the generators
are phased-locked to ensure coherency:

```
100W 100W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL1 SGCL2
```

Here's the setup for determining s11 and s21 with
SGCL2 turned off.

```
100W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm load
SGCL1
```

Here are the results:

```
a1---->|
|---->s21(a1)
s11(a1)<----|
```

THE EM WAVE, s11(a1), EXISTS, IS MEASURABLE, AND IS ALIVE
AND WELL.

Here's the setup for determining s12 and s22 with
SGCL1 turned off.

```
100W
50 ohm load---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL2
```

Here are the results:

```
|---->s22(a2)
s12(a2)<----|
|<----a2
```

THE EM WAVE, s12(a2), EXISTS, IS MEASURABLE, AND IS ALIVE
AND WELL.

Now power off both signal generators and power them up
simultaneously. Let t=0 be the time when s11(a1) and
s12(a2) first exist. Superpose s11(a1) and s12(a2). How
long does it take to achieve b1 = s11(a1) + s12(a2) = 0?
I estimate that time to be delta-t which becomes dt
in the differential equation limit.

The principle of superposition allows us to observe that
s11(a1) and a12(a2) actually existed before they were
canceled.

Here's a little brain teaser for you, Gene.

Given the following experiment with two signal generators
equipped with circulators and load resistors - the generators
are phased-locked to ensure coherency. The two feedlines
are of equal electrical lengths.

100W | 25W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL1 Pfor1=100W--> | <--Prev2=25W SGCL2
<--Prev1 | Pfor2-->

What is the magnitude of Prev1? Pfor2?

> out, is attributing a power to each current -- or each wave -- in the
> first place.

Roy, the intensity equation from the field of optics actually
handles that situation perfectly. The batteries are hooked
up in opposition to each other. Mathematically, their voltages
are 180 degrees out of phase.

Let P1 be the power dissipated in the resistor when battery
#1 is on. Let P2 be the power dissipated in the resistor
when battery #2 is on. P1 = P2

When both batteries are on, the total power in the resistor is:

Ptot = P1 + P2 + SQRT(P1*P2)cos(180) = 0

The intensity equation gets the same total power as you do. If
it's wrong then you are wrong. If it's right then you are wrong.
Seems that you are wrong either way. :-)

Yes, I agree with you, and I think the key factor is that waves are only
free to travel in two directions, and if multiple coherent waves can
travel in the same direction, they are colinear.

> two-radiator situation I proposed. So in a transmission line, we can

But is it possible to inject two coherent waves travelling independently in the same direction? Could I not legitimately resolve the attempt at a circuit node (line end node) of two coherent sources to drive the line to be the superposition of the voltages and curents of each to effectively resolve to a single phasor voltage and associated phasor current at that node, and then the conditions on the line would be such as to comply with the boundary conditions at that line end node. Though I have mentioned phasors which implies the steady state, this should be true in general using v(t) and i(t), just the maths is more complex.

I can see that we can deal mathematicly with two or more coherent components thought of as travelling in the same direction on a line (by adding their voltages or currents algebraicly), but it seems to me that there is no way to isolate the components, and that questions whether they actually exist separately.

So, whilst it may be held by some that there is re-reflected energy at the source end of a transmission line in certain scenarios, a second independent forward wave component to track, has not the forward wave just changed to a new value to comply with boundary conditions in response to a change in the source V/I characteristic when the reflection arrived at the source end of the line? I know that analysis of either scenario will yield the same result, but one may be more complex, and it is questionable whether the two (or more) forward wave components really exist independently.

I am saying that resolution of the fields of two independent waves at a point in free space to a resultant is not a wave itself, it cannot be represented as a wave, and it does not of itself alter the propagation of

either wave. It may be useful in predicting the influence of the two waves on something at that point, but nowhere else.

Having thought through to the last sentence, I think I am agreeing with your statement about free space interference "I maintain that there is actually zero field at a point of superposition of multiple waves which sum to zero, and that no device or detector can be devised which, looking only at that point, can tell that the zero field is a result of multiple waves."

And we haven't mentioned power, not once!

Owen

Thanks Tom.

All noted, and it seems of all wave types, EM waves are most difficult to prove the link between mathematical models and the real world.

To some extent, some of the muddy water is about whether waves superpose (whatever that means), or whether the fields of a wave superpose at a point and those superposed fields do not imply anything about fields or waves at any other points.

If that is the case, it comes back to defining what waves means.

Owen

Hi Owen,

I presume all of this flows from your statement:
>>>A practical example of this is that an omni directional receiving antenna
>>>may be located at a point where a direct wave and a reflected wave result
>>>in very low received power at the antenna, whereas a directional antenna
>>>that favours one or other of the waves will result in higher received
>>>power. This indicates that both waves are independent and available to
>>>the receiving antenna, the waves do not cancel in space, but rather the
>>>superposition occurs in the antenna.

As Roy did not quote any of your material, I must presume this. Am I
correct?

Maybe a 3 foot wde cylinder would be adequate.

One thing: Why are radials so effective? They are not resonant
counterpoises, and from the aspect of surface area in contact with ground,
radials have hardly any surface area that "connects" with "the earth". I can
understand if I put in a 20 foot by 20 foot copper plate flat in the earth
that would "connect" to earth quite well, I mean the measured ohmic
resistance to "the earth" could be quite low. But also capacitive coupling
would be low too. But radials have no real capacitive coupling to "the
earth" neither much surface area in contact with "the earth". So it confuses
me as to why they are so effective.

BTW, since it looks like many wires in the earth are as good as a plate, perhaps I could put in a wire mesh grid about 1 foot under the soil over the whole garden . I'm digging up the garden anyway. Perhaps with some ground stakes here and there connected to the grid, although maybe not necessary.

The only thing that I can think of why radials are effective is nothing to
do with ohmic resistance to "the earth" or capactive coupling to "the
earth". Not even to do with a large surface area in contact with the ground.
It's simply that the ground is changed, those radials simply make "the
earth" in that locality less like an insulator and more like a conductor.
More like the radials make the ground below your feet more like say
a pool of salt water than the high resistivity ground that it normally is.
What do you think?

Hi Owen,

This seems to be in distinct contrast to what appeared to be your goal earlier - insofar as the separation of sources (you and others call them waves). I am trying to tease out just what it was that impelled you upon this thread.

>And we haven't mentioned power, not once!

Not specifically so, but inferentially, certainly. We see the term detector employed above, and it cannot escape the obvious implication of power to render an indication. Perhaps the relief expressed by your sentiment is in not having to have had added or subtracted power (or any other expressions of power).

Hi Owen,

And you have already allowed that superposition does not fail. Thus there must be some other failure to be found in the choice of antenna. From other correspondence, it is asserted that a gain antenna, by virtue of its size, cannot be placed in null space (that point wherein all contributions of energy sum to zero) which is planar and equidistant between sources (there being two of them for the purpose of discussion).

Have I described this accurately?

Hi Richard,

Actually salt water sucks as a local ground - it is as poor a "good"
conductor as you could imagine. Carbon is a far better conductor than
salt water, but no one yet has suggested building on top of a coal
seam.

You would be better off filling your yard with sand to the depth of 30
feet or so (yeah, sure). The testimonials attributed to salt water
comes with its far field qualities of a tremendous mismatch to air and
offering spectacularly low radiation launch angles.

So, copper replaces a very poor conductor (as a first pass
approximation). Invest your copper in close proximity to the base of
the antenna. That is, a lot of short radials, and a fair number of
medium size ones, and a few long ones.

Two things to consider. The ground closest to the antenna is
responsible for efficiency in loading. The ground further out
(between 5 and 10 wavelengths, or more) is responsible for launch
efficiency (offering lower launch angles).

I think it might be more fundamental and perhaps subtle than just a limitation of size. If the null space is a whole plane, as with the two radiating elements of my example, you have an infinite area on which to construct your antenna, although it would have to have zero thickness. But even allowing infinitely thin elements, I don't see any way you can construct it entirely on the plane so it will be more sensitive to signals coming from one side of the plane than the other. That is, use any number of elements you want, oriented and phased any way you want, and as long as all elements lie entirely on the plane, I don't think you can make it favor the signal from one of the radiators over the other. I believe you'll find this same problem with any region of total wave cancellation. I don't have any rigorous proof of this, just intuition from observing the symmetry, and would be glad to see an example which would prove me wrong. (It might reveal a whole new class of directional antennas! Maybe one of Art's Gaussian marvels would do it?) But if I'm right, then there's no way to do as Owen originally proposed, namely to determine entirely from a null space that the null is the sum of multiple fields, let alone the nature of those fields -- at least with a directional antenna. It has to extend out where it can a sniff of the uncanceled fields to do that.

Hmm, a new concept introduced.

I was thinking on these lines.

The first thing to do is to prepare the ground, that is, alter the nature of the ground in the vicinity of the antenna from an electrical point of view. To improve from "poor ground" to "good ground", in an electrical sense. That can be done by laying wires in the ground (radials) or a wire mesh. Once that is done, one is in a better postion to have the best RF ground possible. I think this is what the radial/wires do, they simply alter the nature of the ground where they are placed. This is like making poor ground, good ground or good ground, excellent ground by laying wires in the ground.

Now what seems to be the case is that there is an advantage in making the ground nearest the antenna the very best ground that you can. So, if you are going to use wires to better the ground, make sure that most radials go in near the base of the antenna.

Of course, wires improve the ground, it's conductivity, but in practice, you tend to connect the antenna to the radials/wires rather than make for seperate arrangements.

Yes indeed. But a key realization is that the behaviour on the line
can not depend on arcane details about the construction of the
generator. So when such statements are made, it is instructive
to explore the situation with a different generator. If the outcome
is different, then there is something wrong with the theory. Note
that the standard explanations only require that the impedance
of the source be known. It is not important how this impedance
is achieved. With the hypothesis you are proposing, the internal
details significantly change the behaviour on the line and require
that the line (or the wave) know the internals so that it can
decide to enter or reflect despite the impedance being the same.

> > The conditions on the lines are indistinguishable and yet you

But how does it know, since the output (source) impedances are
the same for both cases? How does the 50 Ohm output
impedance of generator B become infinite while the 50 Ohm
output impedance of generator A does not? This is the key
issue with your explanation. In fact, there is no difference and
they behave the same. The reverse wave encounters 50 Ohms
and is not reflected in either case. It is the only sensible answer.

> closed loop are often flowing in opposite directions.

This is a misunderstanding. Look at the distributed inductors and
capacitors and make the measurements at a point that makes
sense. This is, of course, how a directional wattmeter works.
It measures the voltage and current at one place on the line.
And this is how a real wattmeter would work if it was placed
at the same point.

I think you have made this mistakte before. In my expression P=VI,
V and I are simultaneous instantaneous values and P is the
instantaneous power. If you want average you need to integrate
and divide.

Your expression applies only to sine waves and V and I are peak
voltages. Interestingly, the expression P=V*I*cos(theta) for sine
waves is always derived by starting with Pinst=Vinst*Iinst,
substituting the appropriate functions for Vinst and Inst, integrating
and dividing.

> Forget V and I being 0. cos(theta) is always 0 for a
> standing wave. There is ZERO net power anywhere in a
> standing wave. (It's a lot like my bank account.)

True. But there IS energy flowing at every point that is not a voltage
minimum or maximum. At these points there is NEVER any energy
flowing.

> > Inventive. But it doesn't fly. P = VI or it doesn't.
>
> Forward waves and reflected waves are completely independent

> energy but your zero energy assertions are just illusions.
> EM waves are incompatible with zero energy.

Well that does leave you with a bit of a conundrum since on
an open ended line, zero energy is flowing at every quarter
wavelength point back from the load. Pinst=Vinst*Iinst.
Vinst or Iinst is for all times zero. Power must be zero for
all times.

At such a point a real instantaneous wattmeter would always indicate zero. At other points a real wattmeter would show energy flowing first one way then the other, though the average would be zero. And the peak magnitude of the energy flow depends on where you insert the real wattmeter on the line. An instructive question: Where does the peak energy flow occur? It is zero at every quarter wavelength point so it must be highest somewhere else.

However when you draw the distributed elements, you find
there are many loops (an infinite number?) and each loop
behaves exactly as it does for those in a circuit built of
lumped elements. There is no magic at all. The same
theories work, though the calculus is a bit more tedious.

So the RF is not flowing in opposite directions around the
loop. You just have not drawn the appropriate loops.

The difficulties with your explanations are not so much that they
give you the wrong numerical answers. In fact, they give you the
right numerical answers so often that they convince you of their
truth.

No, the problem is that they lead you to do other thinks wrong.

For example, in all your examples you now provide a circulator
because you think this is the only way to control reflections,
when in fact, all that is necessary is a source impedance that is
equivalent to the line impedance and there will be no reflection.

In other cases you claim that problems are insolvable because
insufficient information is provided about the generator. In fact,
all you need to do is use the source impedance to compute
the reflection coefficient and the problem is solved.

You claim that superposition does not work in a generator.

These examples are suboptimal outcomes that derive
from your explanations. Better explanations do not lead to
these limitations.

Of course, you keep providing examples where the numbers
work and these reinforce your beliefs. You need to temporarily
let go and explore the alternatives. You will find that the
alternatives work better, not because they necessarily
give you different numerical answers but because they free
you to solve more problems and provide more optimal solutions.

Owen Duffy wrote:
>
> But is it possible to inject two coherent waves travelling independently
> in the same direction?

Well, let's see. Begin with two identical, phase locked generators with fixed 50 ohm output resistances. Connect the output of generator A to a one wavelength 50 ohm transmission line, and the output of generator B to a half wavelength 50 ohm line. Connect the far ends of the lines together, and to a third transmission line of any length. Let's properly terminate the third line for simplicity. Superposition should work with this system, so begin by turning off generator A. The one wavelength line is now perfectly terminated and looks just like a 50 ohm resistor across the third line. Generator B puts half its power into generator A's output resistance and half into the third line's load. There's a wave traveling down that line. Now turn off B and turn on A, and note that half of A's power is going to B's source resistance and half into the third line's load. The wave going down the third line is exactly like before, but reversed in phase.

If you believe as I do that waves don't interact in a linear medium and believe in the validity of superposition in such a medium, then you believe that when both generators are on there are two waves going down that third line. They're exactly equal but out of phase, so they add to zero everywhere along the line. With the system on and in steady state, there's absolutely no way you can tell the difference between this sum of two waves and no waves at all. *They are the same.* If you look at the input to the third line, you'll find a point with zero voltage across the line, and zero current entering or leaving it. Where you will get into serious trouble is if you assign a power to each of the original waves. Then you'll have a real job explaining where the power in one of the waves went when you turned on the second generator -- among other problems. There's no problem in accounting for all the power leaving the generators and being, in this case, completely dissipated in their source resistances, without the need for assuming any wave interaction, any waves of power or energy, or assigning some amount of power or energy to each of the two supposed waves.

A solution to the problem based on the assumption that there are no waves on the third line and one which claims there are two canceling waves are equally valid, and both should give identical answers.

Yes, as in the example, there is no difference between no waves at all
and two overlaid canceling traveling waves. They are the same thing.

I maintain that no wave (that is, V or I wave) changes due to another.
While alternative approaches might give correct answers in some cases or
perhaps even every case, the approach I use has proved to adequately
explain all observed phenomena for over a century. So I'll stick with it.

I did cringe at your mention of "re-reflected energy", which would be energy in motion. But at least we don't have power in motion. As soon as that comes into a discussion, it invariably quickly enters the realm of junk science in a desperate attempt to get the numbers to add up -- or subtract, as need be. And I've learned to run, not walk, away from those. (They kinda remind me of overheard conversations at the UFO museum in Roswell. But that's another story.)

Two coherent waves traveling independently in the same
direction in a transmission line are collinear and
interfere in a permanent manner, i.e. they interact. Why
this is so is easy to understand when one superposes the
two E-fields and the two H-fields. The total E-field changes
by the same percentage as does the H-field. In an EM wave,
ExB is proportional to the joules/sec associated with the
wave.

When two coherent EM
waves are superposed while traveling in the same direction
in a transmission line, the total ExB magnitude decreases
if the interference is destructive and increases if the
interference is constructive. A destructive interference
event gives up energy to a constructive interference event
somewhere else. That is what changes the direction and
magnitude of the reflected wave at a Z0-match point. If
the interference is destructive toward the source, the
"extra" energy will be redistributed in the direction of
the load as constructive interference energy.

Thanks Owen, you have just described coherent wave interaction
in a transmission line.

> So, whilst it may be held by some that there is re-reflected energy at

> arrived at the source end of the line?

Yes, wave interaction is permanent. Canceled waves cease to exist in their original direction of travel in the transmission line.

> And we haven't mentioned power, not once!

Every EM wave possesses an E-field and an H-field. The cross product of the RMS value of those fields is proportional to average power. One can avoid mentioning power, but one cannot run away from the fact that the power associated with each EM wave is ExB. If Vref and Iref exist, then the joules/sec in Eref x Href has to exist. The fields cannot be separated from the energy necessary for them to exist. Such is the basic nature of EM waves.

Doesn't

b1 = s11(a1) + s12(a2) = 0

indicate that the two interfering waves are isolated
to a point?

There is a picture in most ARRL antenna books that shows a fan dipole
made from twin lead that just don't work!

Other than that, my experience with fans has been good. They are easy
to adapt to any environment. The same tactics adapt to a vertical
quarter wave as well.

They become indistinguishable, i.e. they interact. If they
interact destructively, they give up energy to constructive
interference in the opposite direction. If they interact
constructively, they require destructive interference
energy from the opposite direction. In a transmission line,
interference is one-dimensional.

Nope - it's a CJ. I guess "stock" may be a misnomer, as I'm not sure what originally came on this thing. I was referring to the common metal tube types.

I would go the other way... the energy can not be separated from the fields.
the fields are the 'more basic' components, energy and power can always be
calculated from them... but you can't always go the other way without
carrying along extra phase information that isn't necessary when talking
about (scalar) power or energy.

Check out http://www.bencher.com/pdfs/00361ZZV.pdf
and http://www.bencher.com/pdfs/00803ZZV.pdf

We usually associate an RF ground with verticals. I believe what you
are referring to as a "long wire" is usually called an :inverted L".

I think your proposed depth of 1 foot or more may be too deep for best
performance.

If you are planning cultivate your garden on a regular basis and use
it for a radial field you have some unique problems. Insulated wire on
top of the ground works as well as buried bare wire.

The consensus seems to be that each time you double your number of
radials you gain a db up to about 128 of them. essentially, more is
better. Popular thinking is that 16 are the minimum.

I experimented with using electrical extension cords of various length
for a radial system and found that all efforts would work but more is
always better! One radial will get you on the air but just barely! I
suspect a quarter wave radiator in any configuration and 4 radials
would beat any mobile installation.

If I were you I would invest in a few orange extension cords and run
them on top of the ground IN the garden rows. Orange will be easy to
see and avoid when you cultivate your garden. They will be easy to
remove and re deploy for garden cleanup.
Plan on assuring the curious neighbors that you are electrically

stimulating your garden. That will probably subdue any objections.

Agreed, but the behavior on the line also doesn't depend
upon where the forward and reverse traveling wave came from.
All that is important is their existence. The reverse
traveling wave might come from a separate source and the
line doesn't know the difference.

> So when such statements are made, it is instructive
> to explore the situation with a different generator. If the outcome
> is different, then there is something wrong with the theory.

No, if the outcome is different, something different is
happening while abiding by the wave reflection model rules.
Why are you surprised that changes occur when something is
changed?

> Note
> that the standard explanations only require that the impedance
> of the source be known.

If the "standard explanations" were correct, this would
have been put to bed a long time ago.

> But how does it know, since the output (source) impedances are
> the same for both cases?

Conclusion: The output source impedance is NOT the impedance
encountered by the reflected wave. That's essentially what
Walter Maxwell's paper says.

> I think you have made this mistakte before. In my expression P=VI,
> V and I are simultaneous instantaneous values and P is the

Interestingly, you forgot to say you were talking about
instantaneous power until now.

> True. But there IS energy flowing at every point that is not a voltage
> minimum or maximum. At these points there is NEVER any energy
> flowing.

Every half cycle in every EM traveling wave, the instantaneous
power is zero. Would you therefore argue that traveling waves
cannot transfer any energy? Please get real.

Given two parallel water pipes carrying 100 gallons/minute
in opposite directions. I can see you arguing that there
is no NET flow of water. But I cannot see you arguing that
there is no flow of water at all when the pressure of just
one stream can knock you off your feet.

> Well that does leave you with a bit of a conundrum since on
> an open ended line, zero energy is flowing at every quarter
> wavelength point back from the load.

The conundrum is all yours. Every half cycle, every EM
traveling wave is at a zero instantaneous power point.
If EM traveling waves can transfer energy while the
instantaneous power is zero every half cycle, superposing
two of them doesn't present a conundrum at all.

> At such a point a real instantaneous wattmeter would always
> indicate zero.

A real instantaneous wattmeter would always indicate zero
at the zero crossing of every EM traveling wave in the
universe so exactly how does the light from Alpha Centauri
ever make it to Earth when the instantaneous power is zero
every half cycle? Please get real.

Again, proved wrong by any number of bench experiments.

> You claim that superposition does not work in a generator.

Not that it doesn't work - just that it is impossible
for a reflected wave to compete with an active dynamic
source. The source essentially ignores the reflected
wave like a fire hose ignores you trying to spit up
the hose against the flow.

> You will find that the alternatives work better, ...

Sorry Keith, I stopped listening to you when you asserted
that I is voltage.

>power. This indicates that both waves are independent and available to
>the receiving antenna, the waves do not cancel in space, but rather the
>superposition occurs in the antenna.

It's really very simple:

at each point in free space at a specific time t, there is only ONE
value of the (vector) electric and magnetic fields,

E=(E_x(x,y,z,t),E_y(x,y,z,t),E_z(x,y,z,t))
B=(B_x(x,y,z,t),B_y(x,y,z,t),B_z(x,y,z,t))

to find those values, you simply add up what comes from various sources
of the fields. Separate antennas do not have their "own" E and B that
is independent.

The key point is that the line conditions did not change, so the
same reflections must be occuring and yet your explanation
claims that sometimes nothing is reflected and sometimes
all is reflected.

> > Note
> > that the standard explanations only require that the impedance
> > of the source be known.

Did you read the same paper I read? I recall that the claim was a
conjugate match of the effective impedances AFTER tuning. The
systems under discussion here have not been tuned for maximum
power transfer.

> > I think you have made this mistakte before. In my expression P=VI,

This is true, but reflection is an instantaneous behaviour.
Simplifying
the analysis to RMS or average values, while often effective, bears
many risks in misleading the understanding, as demonstrated here.

> > Your expression applies only to sine waves and V and I are peak
> > voltages.
>
> I is a peak voltage??????? You are more confused than
> I ever realized. :-)

Oh darn. A typo. I know it will be quoted over and over in subsequent
posts. So be it.

Well, actually two typos. It should read "V and I are RMS voltages
and currents".

> > Interestingly, the expression P=V*I*cos(theta) for sine
> > waves is always derived by starting with Pinst=Vinst*Iinst,
>
> Interestingly, you forgot to say you were talking about
> instantaneous power until now.

My apologies. I did not mean to confuse you. Since reflection is
an instantaneous phenomenon, I just tend to think of it that way.

> > True. But there IS energy flowing at every point that is not a voltage
> > minimum or maximum. At these points there is NEVER any energy
> > flowing.
>
> Every half cycle in every EM traveling wave, the instantaneous
> power is zero. Would you therefore argue that traveling waves
> cannot transfer any energy? Please get real.

Of course not. But when the instaneous power is 0 for all instants
then no energy can be flowing.

> Given two parallel water pipes carrying 100 gallons/minute
> in opposite directions. I can see you arguing that there
> is no NET flow of water. But I cannot see you arguing that

> there is no flow of water at all when the pressure of just

Given one pipe of water, I also would not argue there are 10**9
gallons flowing per minute in one direction and 10**9 gallons
flowing per minute in the other, but the net is 0 so all is well.

That is analagous to the claim being made for forward and
reverse energy carrying travelling waves. Are you arguing
that for the water?

> > Well that does leave you with a bit of a conundrum since on

Except at those points where for every instant the instantaneous
energy transfer is zero.

There is quite a difference between the instanteous power being
occasionally zero and being zero for all instances. Real enough?

Actually, most bench experiments demonstrate the opposite.
Were you to take a moment and look at the schematic for any
typical signal generator, you would find the resistor that matches
the generator to the line and prevents reflection of signals
incident upon the generator.

> > In other cases you claim that problems are insolvable because

It would be educational if you could describe one of these
experiments.

Remember, you are looking for a re-reflection of the reverse signal
at a generator whose source (output) impedance matches the line
characteristic impedance.

> > You claim that superposition does not work in a generator.

Either it works, or it doesn't. Superposition in circuit theory
is not dependant on the relative magnitudes of any of the
sources.

> > You will find that the alternatives work better, ...
>
> Sorry Keith, I stopped listening to you when you asserted

Cecil,

That's typical; you don't have a clue about what you have dragged
yourself into.

Let's see. Delta-t is, uhhhh, delta-t. And of course we can replace
delta-t by the differential form, dt, if we choose. You haven't offered
the slightest justification for this bizarre formulation. Where are the
equations that include delta-t or dt? Sure, Maxwell's equations include
time derivatives, but somehow that does not seem to offer much help for
your delta-t dilemma. I always though that part of the utility of
s-parameters is that they do not have any time dependence in steady
state conditions. Is there some equation for ds11/dt that I missed?

I would sure like to see your definition of "the principle of
superposition" if it somehow says that something existed before it was
canceled. I cannot find that definition in any of my sources.

That is why I hope someone has the documentation.

I have looked through my stuff and cannot find Bill writings.

Bill's antennas were mostly coax fed with NO baluns. He used a center
insulator (his design) and had some unique trap like coils of wire that
he called reactors.

If generator A has 100 watts available to a 50 ohm load, how
much power is being dissipated in the resistor at the end of
the third transmission line?

Did you account for the fact that the generator sees 25 ohms,
not 50 ohms? Are you ignoring the reflections on generator
A's feedline?

> There's a
> wave traveling down that line. Now turn off B and turn on A, and note
> that half of A's power is going to B's source resistance and half into
> the third line's load.

With either source turned off, the voltage reflection coefficient at
the junction of the three lines is rho = (25-50)/(25+50) = -0.33.
Did you account for the resulting reflections?

> If you believe as I do that waves don't interact in a linear medium and

> get into serious trouble is if you assign a power to each of the
> original waves.

Would you agree that the waves are EM waves? Would you agree
that the waves each have an E-field and a B-field? Would you
agree that the joules/sec in each wave is proportional to
ExB and that the waves could not exist without those joules/sec?
There is absolutely no problem assigning joules/sec to each

EM wave. In fact, the laws of physics demands it.

> Then you'll have a real job explaining where the power
> in one of the waves went when you turned on the second generator --
> among other problems.

It's no problem at all. Optical physicists have been doing it
for over a century. The energy analysis at the feedline junction
point is very straight forward. It simply obeys the wave reflection
model, the superposition principle, and the conservation of
energy principle.

> A solution to the problem based on the assumption that there are no
> waves on the third line and one which claims there are two canceling
> waves are equally valid, and both should give identical answers.

EM waves cannot exist without ExB joules/sec, i.e. EM waves
cannot exist devoid of energy. Those two waves engaged in
destructive interference which redirected the sum of their
energy components back toward the sources as constructive
interference. They interacted at the physical impedance
discontinuity and ceased to exist in the third feedline.

In your example, with both sources on, the SWR on the two
generator feedlines is infinite. There is exactly enough joules
stored in each line to support the forward and reflected powers
measured by a Bird directional wattmeter.

Many of us miss Bill, W9INN, and have had years of enjoyment from his FB antennas. When I purchased my antenna from Bill in 1977 or 1978 he provided excellent documentation that I have lost.

Did anyone take the time to scan Bill's documents or have they been saved in a library somewhere?

I would like to get the specifications on his 40/80 "resonactor"(his term for a trap) so mine can be rebuilt.

What started out life as a 40/80 dipole from W9INN was modified by me to add extra sets of wires for 10 MHz and 18 MHz and I got lucky the whole mess works FB on 24 MHz as well as 50 MHz. The antenna has been up for 25++ years and still works great.

W9INN you are missed!

That is why I hope someone has the documentation.

I have looked through my stuff and cannot find Bill writings.

Bill's antennas were mostly coax fed with NO baluns. He used a center
insulator (his design) and had some unique trap like coils of wire that
he called a resonactor.

Hi Richard,

Yes, this is a good analogy. It fails quickly, however. That is, you
do not gain better ground characteristics in proportion to the number
of radials.

So, as general rules go, the common advice is to make your radials as
long as the radiator is high, and to lay out as many as you feel
comfortable doing. If you need a hard number, then a dozen to sixteen
is a good starting place from which others can argue ceaselessly to
offer you to gain only 1 more dB of performance (maybe 2).

>Now what seems to be the case is that there is an advantage in making the

>
>Of course, wires improve the ground, it's conductivity, but in practice, you
>tend to connect the antenna to the radials/wires rather than make for
>seperate arrangements.

True, that is the sense of a counterpoise. However, even a ground
field beneath a dipole overhead improves the dipole's performance and
there is no direct connection there. Some would argue this only
describes a yagi pointing straight up and the gain only comes to more
power poured into the clouds. Yes, this is an appealing argument, and
yet if you consider how much the gain rises at a low angle of launch;
then you find it is beneficial in that respect as well.

The alternative view of radials is that they operate as a shield
against loss.

I don't recall Maxwell's equations relying on "voltage and
current waves".

> The key point is that the line conditions did not change, so the
> same reflections must be occuring and yet your explanation
> claims that sometimes nothing is reflected and sometimes
> all is reflected.

If you put two signal generators equipped with circulator
loads at each end of a transmission line, there are absolutely
no reflections anywhere. Yet there is a forward wave and a
reverse wave. We can cause a reverse wave when "sometimes
nothing is reflected and sometimes all is reflected". The
transmission line will not know the difference.

> Did you read the same paper I read? I recall that the claim was a
> conjugate match of the effective impedances AFTER tuning. The
> systems under discussion here have not been tuned for maximum
> power transfer.

The existence of a conjugate match is irrelevant to our
discussion. All that is relevant to our discussion is
that the reflected waves does not see the generator
source impedance.

> Oh darn. A typo. I know it will be quoted over and over in subsequent
> posts. So be it.

Keith, arrogant omniscient beings, as you present yourself

> Of course not. But when the instaneous power is 0 for all instants
> then no energy can be flowing.

The instantaneous power is zero every 1/2WL in an EM wave.
Therefore, according to you, EM waves cannot transfer energy
or power. Good luck on that one.

> There is quite a difference between the instanteous power being
> occasionally zero and being zero for all instances. Real enough?

If the instantaneous power is zero for all space and time,
an EM wave cannot exist.

Hi Roy,

I presume by your response that it affirms my description. Moving on
to your comments, it stands to reason that the reduction of the
argument proves you cannot build an antenna with directivity within a
very specific constraint - the null space. As there is zero dimension
on the axis that connects the two sources, then no directivity can be
had from a zero length boom as one example. Other examples would
demand some dimension other than zero along this axis is where I see
the counter-argument developing.

>... But if I'm
>right, then there's no way to do as Owen originally proposed, namely to
>determine entirely from a null space that the null is the sum of

>directional antenna. It has to extend out where it can a sniff of the
>uncanceled fields to do that.

This then suggests that there is something special about null space
that is observed no where else. That is specifically true, but not
generally. What is implied by null is zero, and in a perfect world we

can say they are equivalent. Even a dipole inhabiting that null space would bear it out, whereas an antenna with greater directivity along that axis would not.

However, if we open up the meaning of null to mean a point, or region, within which we find a minimum due to the combination of all wave contributions, then I would say a directive antenna is back in the game, and that it exhibits Owens proposition (if I understand it - but I still need to see Owen's elaboration).

> approximation). Invest your copper in close proximity to the base of
> the antenna. That is, a lot of short radials, and a fair number of
> medium size ones, and a few long ones.

Exactly...

In fact, one can do some numerical analysis to figure out an optimum strategy, based on minimizing IR losses in the soil. The current density is higher close to the base of a vertical, so, at first glance, it would appear that improvements in conductivity there would have more "value". I imagine there's some nice integration that covers it all.

All that analysis and spreadsheets out there all make the assumption that you want all radials the same length, which isn't necessarily so.

What also throws a "wrench into the gear train" is that if you start looking at verticals with nonuniform current distributions, especially if they aren't representable by a "simple" form such as linear or cos(h), an analytical approach gets tricky (hence the suggestion for numerical methods). Consider, for instance, a half wave dipole with the

center, say, 3/8 wavelength above the ground. Or some sort of asymmetric vertical with an elevated feedpoint, or loading coils. The optimum radial layout gets a bit trickier to figure out.

He may notice a resonant point around 27-28-29 mhz also..
If you use a length a coax to feed, that will add a 1/4 wave
of length to the 80 legs, IE: about 60-70 feet, you can feed
the shorted coax end from the shack, and run it on 160m as
a vertical. When I use the 40 legs for 15m, I usually slap a
tuner inline as a line flattener to keep the radio happy, and
also increase the usable bandwidth. I usually don't trim the
40 antenna to get a match on 15, as I prefer the 40 legs to
be tuned where I cut it, which is usually in the middle of the
band, so I can work both phone and CW. Any cheap tuner
will easily give a good match for 15m, and the loss is going
to be low, being the match isn't bad to begin with.
In the old days with tube rigs, I never worried about tuning 15.
The rigs would tune it no problem, with no tuner required.
But the newer solid state radios are a bit pickier.. So I'll
put the tuner on. I have a 989c which is always inline, but
rarely actually used in most cases, except for the meter,
and in rare cases like 15m, 30m, and maybe 160m where
I want to tweak the match a bit.

I find that trying to prune/tune a multiwire antenna (like a fan) is an exercise in frustration because of the strong interactions among the elements, aggravated by the fact that most people install antennas in places other than a vacuum. there's wind blowing (which changes the spacing), trees, other stuff, etc.

So, I figure that if you get it "reasonably close", and then use an autotuner to deal with the rest. If you want to obssess about loss in the feedline, then put the tuner at the feedpoint.

Yes, the tuner costs some money, but it's a one time investment, and makes playing with wire antennas much more pleasant and fast. Once you've got that tuner, you can literally build decent antennas in 10 minutes with parts from the grocery store.

If you get a tuner that has a computer interface, then you can use it to measure the Z of the antenna, if you feel compelled to prune.

Hi Richard,

Actually, it was posted because of doubt about your claim "Remove the
load, and you remove interference." Please describe this phenomenon
in more detail. The implications are huge.

Thanks,

Jim AC6XG

Hello again Richard,

Seems we're having some difficulty communicating so I'll do you the favor that you rarely extend to anyone, and speak as plainly as possible. The subject matter is interference; a result of the superposition of waves. Your assertion regarding the phenomenon is: "No load, and any issue of canceling fields is strictly limited to what goes on between the ears."

My question, plainly put is: What in the hell are you talking about?

Thanks and regards,

Jim, AC6XG

Hi Jim,

This quote of mine is simply an example of poetic license, it is to suggest that without a load, interference is a concept trapped in the mind and unrealized = there is no interference. You asked several times about what do the waves DO, and certainly this was one of many expressions I've offered that responded to that. I didn't see why repetition was necessary, or that I had to construct yet another elaboration, unless you were fishing for stylistic variation. I would be happy to go there! ;-)

It helps to know what your doubt was about, as we would have gone around the track several times to home in on one sentence.

> demand some dimension other than zero along this axis is where I see
> the counter-argument developing.

In the two antenna example, the null space is a plane. Since the plane is infinite in extent, you can create in that plane an antenna with a boom of any length, and therefore with arbitrarily high directivity. However, if you restrict that antenna to lie entirely in the null plane, that directivity won't be in a direction such that the antenna will favor one radiator over the other. Therefore it can't tell if the null plane is simply an area in space with no field, or whether it's the result of two superposing fields. And I believe this is true for any antenna, of any size, orientation, or design that you can construct which lies completely in that plane.

> This then suggests that there is something special about null space
> that is observed no where else. That is specifically true, but not
> generally. What is implied by null is zero, and in a perfect world we
> can say they are equivalent. Even a dipole inhabiting that null space
> would bear it out, whereas an antenna with greater directivity along
> that axis would not.

But I'm claiming you can't get directivity such that you can favor one radiator over the other, by any antenna lying entirely in the null space. In other words, any antenna you build in that null space will detect zero field. The special thing about null space is simply that it's a limit, and it makes a good vehicle for illustration because we can more easily distinguish between nothing and something than between two different levels.

> However, if we open up the meaning of null to mean a point, or region,
> within which we find a minimum due to the combination of all wave
> contributions, then I would say a directive antenna is back in the
> game, and that it exhibits Owens proposition (if I understand it - but
> I still need to see Owen's elaboration).

I'll extend my hypothesis to include all such regions. Create a null space or region of any size or shape by superposing any number of waves. I claim that any antenna, regardless of size or design, lying entirely in that space or region will detect zero signal. In fact, no detector of any type which you can devise, lying entirely within that null space or region, will be able to detect anything or otherwise tell the difference between the superposition and a simple region of zero field. It will take only a single contrary example to prove me wrong.

Roy Lewallen, W7EL wrote:
"With the system on and in steady state, there`s absolutely no way you can tell the difference between this sum of two waves and no waves at all."

With the constraint of where Roy would let me check, I think he is right.

Terman`s first sentence in the 1955 (4th edition) of "Electronics and Radio Engineering" is: "Electrical energy that has escaped into free space exisrs in the form of electromagnetic waves."

Other definitions say: "All entities that carry force, whether one marble striking another or sunlight moving molecules of air, act sometimes as particles and sometimes as waves."

Thyere is an analogy of Roy`s null plane in public address where two loudspeakers are placed together and driven out-of-phase. The microphone is placed on the centerline to avoid feedback.

I agree that two wires in a plane with the plane of the source antennas perpendicular to the plane of of those wires and the reception point equidistant from the antennas cannot select between those antennas without occupying some space outside the plane. A patch antenna might do it but it has depth or thickness so it partially falls outside the plane.

Waves may be only a mathematical convenience but are visible in water and in powders on vibrating surfaces. They are also visible in synchronized illumination on vibrating surfaces and in synchronized photos.

Waves in-phase and traveling in the same direction are inseparable so might as well be a single wave.

Best regards, Richard Harrison, KB5WZI

> spacing), trees, other stuff, etc.

Thats why I always spread them apart. I never stack the elements,
or have them closely spaced. I'll place them at right angles,
if only two bands.. The third band, I'll usually stick equally
between the others. If you have a coupling problem with
the third band, often just moving that leg a few feet one
way or the other will cure the problem. Once you do that,
you won't have wind problems with the higher band.
The only other type "all band" dipole I use is the "sectioned"
dipole, where you use insulators, and clips to open/short the
overall length of the dipole for other bands. But I only use those
when camping when I can only string a single wire.

>
> So, I figure that if you get it "reasonably close", and then use an
> autotuner to deal with the rest. If you want to obssess about loss in
> the feedline, then put the tuner at the feedpoint.

Most of the time the loss is not a big deal. Only on the "hi Z"
bands,
where the antenna is a full wave, etc, will it be a problem. And even
then, you can still operate. I use 213 coax, so if the SWR is under
say 5:1, and I'm on a fairly low frequency, the loss is not a big
deal.
That's about my scenario on 30m, where I have no resonant elements.
Still works quite well.
>
> Yes, the tuner costs some money, but it's a one time investment, and
> makes playing with wire antennas much more pleasant and fast. Once
> you've got that tuner, you can literally build decent antennas in 10
> minutes with parts from the grocery store.

Maybe so, but I can do the same without a tuner too...
I don't use a tuner on the normal "resonant" bands.
A coax fed dipole is my favorite 10 min "quicky" antenna.
The only cost is coax and a bit of wire. No tuner
needed, and the system efficiency is hard to beat.
My 989c will handle open wire feeders, but I don't use them much.

>
> If you get a tuner that has a computer interface, then you can use it to
> measure the Z of the antenna, if you feel compelled to prune.

Actually, I can probably do it faster from sense of smell... :/
I find the same thing using the analysers... I can often tune
an antenna faster the old fashioned way, then using the new
fangled analysers.. I don't own an analyser myself, but I
have tried the MFJ versions that friends of mine have.
I'm too cheap to buy one, thats for sure... All it does is
verify what I can already see using the old methods.. :/

You are implying that they must have a zero value.
If that is true, an s-parameter analysis is an
exercise in futility.

I'll make it easy for you.

s11(a1) = 5 at zero degrees

s12(a2) = 5 at 180 degrees

b1 = s11(a1) + s12(a2) = 0

Is s11(a1) = 0? _______

Is s12(a2) = 0? _______

Is b1 = 0? ______

> me as to why they are so effective.

To put it simply, rather than couple with the earth, they help shield
the antenna
currents from the lossy earth..
IE: Richard Clarks comment..
"The alternative view of radials is that they operate as a shield
against loss."

Thats about what it boils down to...
In fact, I think 60 radials one inch off the ground should be slightly
better
than 60 radials touching the ground, both using bare wire.
But radials that are elevated to any real height should be resonant
for
best results.
>
> BTW, since it looks like many wires in the earth are as good as a plate,
> perhaps I could put in a wire mesh grid about 1 foot under the soil over the

> stakes here and there connected to the grid, although maybe not necessary.

Would be ok, but actual radials are a better use of wire, than mesh.
Also
mesh can develop connection problems on down the line.
Mesh has an equal density over it's whole area.
But radials place a higher density of wire at the feedpoint, which is
what you want. The ground area at the feedpoint is the most critical.
But that doesn't mean you want to ignore the area a bit farther out.
Normal radials spoked out from a center give you a good appx overall
density of wire in the areas you want to have it.
In general, for a given amount of wire on the ground, many shorter
radials are better than a few long ones. That places more of the wire
at the feedpoint.

A cylinder or tube, etc makes a lousy rf ground. The lightning ground
is
the one that needs a super good connection to earth.
The RF ground requires *no* connection to earth to function properly.

Thanks Cecil, I have been wanting to put up an antenna like yours for
quite a while now. Today I was doing a liittle clean up in the attic
and found a box of DPDT open frame relays that should work well for
remote switches. I should be able to run coax out to my garden shed
and and ladder line from there to the antenna locating the switches at
the shed. I can hang the dipole at about 40ft and was wondering what
the pattern would be. I was thinking this low to the ground it would
be almost an omni- directional antenna. If I could ever get all my
crap organized I could probably put together one hell of a station.

Hi Roy,

No dispute there either.

>The special thing about null space is simply that
>it's a limit, and it makes a good vehicle for illustration because we
>can more easily distinguish between nothing and something than between
>two different levels.

That is distinctive as being binary, certainly; but I am sure there is
something between two different levels that are distinguishable to the
same degree. The difference between 0 and 1 is no greater than
between 1 and 2.

>> However, if we open up the meaning of null to mean a point, or region,

But this says nothing of the quality of "null" as I extended it above
which could be supported by a directional antenna. As I am still
unsure of the nature of Owen's proposition, I will leave the quality
of "null" for Owen to discuss or discard.

> electromagnetic fields are there and they are not there.

You seem not to be able to separate the past from the
present, Jim. The electromagnetic fields were there
and now they are not there any more. Here is a before
and after example for you.

Given the following experiment with two signal generators
equipped with circulators and load resistors - the generators
are phased-locked to ensure coherency. The two feedlines
are of equal electrical lengths.

SGCL1 is turned on. SGCL2 is turned off.

100W | 25W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL1 <--Prev1 | SGCL2

What is Pref1 before SGCL2 is turned on? What is Pref1
after SGCL2 is turned on? Did Pref1 change after SGCL2
is turned on?

Since Pref1 *NEVER* encounters the impedance discontinuity
how can it possibly be affected by SGCL2 being turned on?

Gene Fuller wrote:
> Where are the equations that describe this "delta-t" stuff that you keep
> bringing up?

Actually, Gene, the example I just posted for Jim will answer
your question.

SGCL1 is turned on. SGCL2 is turned off.

100W | 25W
50 ohm---50 ohm line---+---291.4 ohm line---291.4 ohm
SGCL1 <--Prev1 | SGCL2

When SGCL2 is turned on let t=0 be the time when the
SGCL2 source wave reaches the impedance discontinuity
at point '+'. How long does it take for that source
wave to affect Prev1? Whatever length of time that is,
that's the length of delta-t.

This is a technique to compensate for moving the datum.

I am not saying it won't work, and I can see that you have done it to reduce
the size of accurate table needed to register the device.

There is no reference to time in an s-parameter analysis. That is because it assumes steady state. The purpose of doing analysis in the steady state is because past and present are irrelevant. S-parameter analysis doesn't support your claim. There is no support for your claim.

And yet is does work. For 39 holes in my case.

I didn't say it was highly accurate, but that by following what I did,
that it would work well enough for a long boom UHF beam DESPITE that
fact. It's also cheap and easy. Unfortunately, many of us cannot
afford the best, but need still need good results. This is one way.

If I could afford equipment like you describe, I would certainly have it
and use it, but I can't. My guess is that most of the people here are
closer to my end of the spectrum than yours. Yet another unfortunate fact.

The trick I have found..

Is to space the wires 12 inches apart, as close to the feed point as possible.
With my antenna, it goes from the feed point to a 12 inch separation 18 inches from the feed point.
The wires are 12 inches apart from that point on and there is very little interaction between the wires if any. At least my antenna analyzer cant find any.

Like I said, the trick is to move the wires away from each other as close to the feed point as possible.
I have found with this set up, that wind etc. changes very little.

Like I have stated before, my wires are hung under each other, so I have no idea if the same concept would work with a true fan dipole....

This is steady-state after the wave interaction. What
you guys don't seem to realize is that s11(a1) and
s12(a2) are continually changing, continually
interacting, and a1 & a2 are rotating phasors
changing with time.

Richard

I still have a problem reconciling the resultant E field and H field, including their direction, with the concept that they are not evidence of another wave. I am not suggesting there is another wave, there is good reason to believe that there isn't, but that if there isn't another wave, is the resultant E field, and H field (including direction) a convenient mathematical representation of something that doesn't actually exist.

In answer to your last question, a quest for understanding. I don't know the answer, but the discussion is enlightening.

Basically. Some of the problems in the analysis are as a result of trying to determine conditions at a point, which can have no area, and presumably no power, but yet E field and H field.

I think the discussion is mainly exploring a detailed definition of the concept of superposition of radio waves. It seems to mean different things to different people, but it is used as if it has a shared meaning.

It is usual, I believe, to talk about power density. Volts per meter times amps per meter is watts per square meter. It's not watts at a point, or along a line, but over an area. Of course, you have to be careful what you mean by that. The actual value of the power density will be a function of position and time, of course, and will in general be different at one point than at a point a meter, a millimeter, or a micron removed. It can also be useful to add the dimension of frequency: the power density is also a function of frequency.

> I think the discussion is mainly exploring a detailed definition of the

One of the points of the "fields are interpreted by some as physical, and by others as mathematical abstractions," which is a preamble to further antenna discussions in the book I'm thinking of, is that it doesn't matter which way you view them; if both camps describe their behaviour the same way, the observable result is the same.

Cheers,
Tom

Tom, I don't understand the reference to expensive equipment, the system I described of placing a short close fitting rod in the first hole and visually aligning the rod with the drill for each additional hole is very low cost and adequately accurant.

Superposition means the following: If f(x) is the result of excitation x and f(y) is the result of excitation y, then the result of excitation (x + y) is f(x + y). This is a very clear and unambiguous definition which you can find in a multiplicity of texts. It's an extremely valuable tool in the analysis of linear systems.

To put it plainly in terms of waves and radiators, it means that if one radiator by itself creates field x and another creates field y, then the field resulting when both radiators are on is x + y.

What other meaning do you think it has?

Owen

I was refering to another of your posts -

Wes, I agree, that is entirely practical. As far as bubble technology goes, senstivity easily exceeds that, IIRC the plate bubble sensitivity on theodolites is commonly around 20" (seconds) per 2mm run. By reversing such a bubble and splitting the difference, it should be possible to achieve an error well under 0.1mm/m slope.

Realistically, most bubbles for engineering workshop use would be more accurate than the drilling process, so they are a quite adequate means of registering the work.

As has been described and documented in the last few months (not here, but in science journals), emails, and their equivalent, are sometimes the most misunderstood things in the history of human communication. The problem is even worse in a newsgroup, because the threads are huge, and replies sometimes reference posts not in the current sequence, and people receive items out of time order and often delayed.

Sometimes works on Windows/Apple

http://users.fulladsl.be/spb13810/linux/radio.txt

20000+ other packages listed on:

http://users.fulladsl.be/spb13810/linux/software.txt

The French parliament is going to use Ubuntu.com linux as of this summer.

about this packages and this text:

Because I was unhappy I did not have a simple means to search the index of all packages linux (in fact debian) gives me, I made a long text file which consists of the package name, followed by its detailed information (if it exists). That makes a file of about 15Mb, and 280.000 lines. Now, people that DO NOT have linux can do a word search on this file, and will soon see what applications interest them. Of course, I know this file contains some overhead, but if you choose your search key well, the result will be better ...

Here is the list:
http://users.fulladsl.be/spb13810/linux/software.txt

Comments on typography are always welcome ... (I made this in a hurry, so I'll change it anyway)

(In fact, it should be easy to make a html, but I won't spend too much time now.)

Is there anybody that knows about this kind of text with all pkg included??
Of course, I know, if you have linux, you can start Synaptic, and do a search there, but non linux users can't do that, and this is like a paper dictionary: you look at a term, and you can let your eyes wonder around for other terms, so that you learn things you didn't expected.... (and you could search internet, or eg http://packages.ubuntu.com/edgy/ , but ... too much clicking involved ...)

PS: if you are lucky, this software exists for you PC/ windows or for your mac ...
But a linux install is less trouble, then you have ONE application which shows all 20000+ software packages, one click, and they are installed.
On a platform like Windows, you need to surf to 20000 websites, download implicitly, and install yourself. On Apple, you can use fink, and sometimes reach 5000 packages, but you need to be a half unix expert, so yo can better start of linux anyway ...

I guess that's the definition of linearity. I'm not sure I've heard
it called superposition before, but rather that the superposition
theorem is a direct result of the linearity of a system. I trust
that's a small definitional issue that doesn't really change what
you're saying.

Cheers,
Tom

I reckon that if you can't see them, measure them separate them etc,
then they don't exist.
It's different to being in a null between two antennae. The signals
don't appear to exist where you are, but move directly away from either
antenna, and there they are. So they exist at the null even though you
can't see them there.

4871. Where does the far field start on a phased array?

Newsgroup: rec.radio.amateur.antenna

Source record: 42469

First, I should state this is not a question about an amateur antenna system, but I'm hoping someone may know the answer.

Consider a phased array of antennas. There are some 30 or so antennas all in a line, as below, where "A" is an antenna and "-" indicates a space

A---A---A---A---A---A---A---A---A---A

The overall width of the array is D.

The radiation pattern varies as a function of distance from the antenna until one is in the far-field. But where does the far-field start for a phased array? Can one use the normal formula of

2 D^2 / lambda ?

If the width D is large (say 30 m) and the wavelength small (say 0.1 m), then the far field does not start for

2 * 30 * 30 / 0.1

18,000 m
= 18 km

i.e. the radiation pattern is a function of distance until you are some 18 km (about 11 miles) from the antenna.

If anyone can give me a link to a professional reference on this, scientific paper etc, that would be useful.

Fine Roy, the maths is easy, but you don't discuss the eligible
quantities.

As I learned the superposition theoram applying to circuit analysis, it
was voltages or currents that could be superposed.

Presumably, for EM fields in space, the electric field strength and
magnetic field strength from multiple source can be superposed to obtain
resultant fields, as well as voltages or currents in any circuit elements
excited by those waves.

For avoidance of doubt, power is not a quantity to be superposed, though
presumably if it can be deconstructed to voltage or current or electric
field strength or magnetic field strength (though that may require
additional information), then those components may be superposed.

The resultant fields at a point though seem to not necessarily contain
sufficient information to infer the existence of a wave, just one wave,
or any specific number of waves, so the superposed resultant at a single
point is by itself of somewhat limited use. This one way process where
the resultant doesn't characterise the sources other than at the point
seems to support the existence of the source waves independently of each
other, and that there is no merging of the waves.

Is anything above contentious or just plain wrong?

Owen

Rather a non-sequitor since we were discussing what was happening
at the generator end, but non-the-less true and demonstrates again
one of the greater weaknesses in your learnings. You really do need
to realize that there is no need for a circulator. Once you are beyond
this, many things will fall into place.

There you go. Still stuck. You really should crack the books in search
of a reference to support your contention. You won't find one.

And the relevence of the conjugate match is that the conjugate
is the generator source impedance and it is the impedance that
the wave incident upon the generator sees.

Nothing to sweep under the rug, I am afraid. It is key that the
dissipation depends on the design of the generator. Some
times those 'reverse watts' cause the dissipation to drop
to 0, sometimes they cause it to increase by a factor of 4,
sometimes they cause it to increase by the numerical value
of the 'reverse watts'. Pretty much hard to argue that those
'reverse watts' are real when their heating effect is so
variable.

> > Either it works, or it doesn't.
>
> Superposition works in some situations and doesn't work

I'd suggest you think of power as a quantity not a situation.
Superposition works for linear, time invariant circuits with
multiple sources. Check any text book. The generators and
lines under discussion meet these requirements.

I realize the results of superposition are inconvenient for
your explanations, but it would be better to examine your
explanations than to discard superposition. You will then
be free to use superposition to solve problems you
currently consider unsolvable.

linearity of the system is VERY important. it is what prevents the
waves/fields from interacting and making something new. empty space is
linear, air is (normally) linear, conductors (like antennas) are linear.
consider a conductor in space. if 2 different waves are incident upon it
you can analyze each interaction separately and just add the results.
However, if there is a rusty joint in that conductor you must analyze the
two incident waves together and you end up with not only the sum of their
resultant fields, but also various mixing products and other new stuff. so
yes, linearity is a very important consideration when talking about multiple
waves or fields and assuming superposition is correct.

yes, superposition is meant to work directly on voltage, current, electric fields, and magnetic fields. it can be extended by adding appropriate extra phase terms to power or intensity as cecil prefers to use.

you are at least partially correct. a measurement at a single point at a single time can only give the sum of the fields at the instant of measurement. make a series of measurements at a point over time and you can infer the existance of different frequency waves passing the point, but not anything about their direction or possibly multiple components. add measurements at enought other points and you can resolve directional components, polarization, etc. assuming your points are properly distributed... this means that a small probe (like a scope probe) can only make a record of voltages/currents or fields at a single point and can't tell anything about direction. add a second probe and you could detect the direction of travel of waves on a wire.

> Utter nonsense. Any setup that includes t0 or t=0 is not steady state.

Gene, you obviously misunderstood what I said. There is
no t0 or t=0 in my above statement. It is just that the
delta-t doesn't change from the transient state to the
steady-state.

In an s-parameter analysis:
The normalized voltage, a1, equals Vi1/SQRT(Z0) where
'i' stands for incident voltage. a2 equals Vi2/SQRT(Z0).
These voltages are normally represented in phasor
notation but they can just as easily be represented
in exponential notation where a1 = Vi1*e^jwt+X and
a2 = Vi2*e^jwt+Y, where X and Y are constant phase
angles. Thus, the s-parameter equation becomes:

b1 = Vi1[cos(wt+X)]/SQRT(Z0) + Vi2[cos(wt+Y)]/SQRT(Z0) = 0

adding the delta-t "tick" gives:

b1 = Vi1{cos[w(t+delta-t)+X]}/SQRT(Z0) +
Vi2{cos[w(t+delta-t)+Y]}/SQRT(Z0) = 0

Vi1 obviously has to be an equal magnitude to Vi2 and
X and Y obviously have to be 180 degrees apart. Given
that, for every delta-t "tick" of time, the two real
normalized voltages sum to zero. The square of the
normalized RMS value gives average power in each
wave. The equation can be turned into a differential
equation by having delta-t approach zero in the limit.

Now the big question is: Is superposition always reversible?
If not, it implies interaction between f(x) and f(y).

So is superposition always reversible? If not, that would
imply interaction between the superposed components.

The single bit of additional information required is the phase
angle between the voltages (or currents or fields). Optical
physicists deduce the relative phase angle by the ratio of
intensity (power density) in the bright rings vs the dark rings.
We hams can deduce the relative phase angle by the ratio of
forward power (density) to reflected power (density). Our task
as hams looking at a one-dimensional transmission line is much
easier than the task of optical physicists looking at visible
light in three-dimensional space. Our transmitted CW signals are
coherent and collinear in a transmission line, something that
optical physicists can only dream of.

> The resultant fields at a point though seem to not necessarily contain

> other, and that there is no merging of the waves.

That is the case in a majority of examples. But in the case
of two coherent collinear waves superposed in a one-dimensional
transmission line where the resultant is the same at every point,
we can safely assert that those two waves have ceased to have an
existence independent of each other. The idea of two waves
canceling all up and down the transmission line yet continuing
their separate existences until their combined zero energy level
is dissipated (or not) is a pipe dream. If ExB = 0, the energy
in those canceled waves went the other direction a long time ago
and those waves have ceased to exist in their original direction
of travel, i.e. they have interacted and canceled.

When two waves combine to a zero energy level, the pre-existing
energy in those two waves is "redistributed in the direction
of constructive interference". In a one-dimensional transmission
line, there are only two possible directions. If waves superpose
to zero energy in one direction, their energy components are
"redistributed" in the only other direction possible. If the energy
ceases to flow in the reverse direction, then it must flow in the

forward direction. That's why Pforward = Psource + Preflected.
Anything else would violate the conservation of energy principle.

I see you have not yet read Walter Maxwell's article. The
generator source impedance is not what is seen by the reflected
waves.

> I have certainly never said that. If you could point me to the words

> misunderstanding.

Correct me if I'm wrong. I understood you to say that energy
cannot flow past an instantaneous zero energy point yet there
is an instantaneous zero energy point every 1/2WL in an EM
traveling wave.

No, I agree entirely, except for

>This one way process where
>the resultant doesn't characterise the sources other than at the point
>seems to support the existence of the source waves independently of
>each other, and that there is no merging of the waves.

which I don't understand. We lose information when we add or otherwise operate on two numbers to get one. (Which I think is what you might be saying.) Given a number which is the sum of two others, we can't tell from that sum alone what the two original numbers were. The same is naturally true of superposed or added, if you prefer, waves or fields. Power has the same problem (among others) -- given even an instantaneous power, we can't tell without some other information (such as the complex impedance) what the constituent voltage and current were.

Ignore it if you choose. That's when the present hoopla
began, at least in the amateur radio community. You can
follow the thread from that point to the present to see
what is happening in the present.

> 'reverse watts' are real when their heating effect is so
> variable.

Not at all. The heating effect depends upon how much of
the reverse joules/sec are re-reflected. If the dissipation
drops to 0, that is prima facie evidence that all the
reflected joules/sec have been re-reflected. If the
dissipation increases by a factor of 4, that is prima facie
evidence that all of the reflected joules/sec are being
dissipated in the source along with all of the joules/sec
available from the source into a matched load. Anything
else would violate the conservation of energy principle.

> I'd suggest you think of power as a quantity not a situation.
> Superposition works for linear, time invariant circuits with

But superposition obviously doesn't work at the source
point. One possible technical conclusion may be that
the dynamic active source is constant, fixed, and refuses
to be superposed (for any constant, fixed load). If that
is true, it would certainly stop the present raging debate
in its tracks.

That seems to be common knowledge except for some
(narrow-minded?) posters here. Powers do not superpose
but there is a method of adding power (densities)
that has been acceptable to physicists for at least
a century and may date back to Young, Fresnel, and
Huygens.

This is really interesting. Given the following:

b1 = s11(a1) + s12(a2) = 0

Let P1 = |s11(a1)|^2 = 1 joule/sec

Let P2 = |s12(a2)|^2 = 1 joule/sec

Therefore, Ptot = |b1|^2 = 0 joules/sec

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(180)

Ptot = 1 + 1 - 2 = 0 joules/sec = |b1|^2

Can one reverse the superposition whose result is
zero to recover the original two component waves?
If not, isn't that proof that the two original
component waves interacted?

Hello,

Your formula for far field distance (Fraunhofer region) assumes a path
difference between the inner and outer antenna with respect to an

observation point of 1/16 lambda.

The 1/16 lambda (22.5 degrees) path difference is used by many experts (for example page 39 of "Antennas for all applications" 3rd edition [Kraus, Marhefka]).

Depending on your application and required accuracy, you can divert from the 1/16 lambda rule. For example when you taper the power distribution for your array (to get lower side lobes), the far field distance is not that far. If you accept a 1 dB error in main lob gain, you can go down to 25% of the far field distance formula. However when you want to measure a dip in the radiation pattern of (for example) -50 dBi, you might need a larger distance.

For your array, you can calculate the effect of distance on radiation pattern in a spread sheet program.

Best regards,

Wim

no, because you have done a non-linear operation on them by converting to
powers. obviously at the start 'a1' and 'a2' are separate.

i should expand a bit more. all your equations above have done is shown
that at the point where you are doing your analysis s11(a1) and s12(a2),
which add up to 0... also produce a net 0 power at that point. this is as
expected for destructive interference AT THAT POINT. as such your s
parameter analysis is insufficient to separate the individual components
after you combine them into a power. however, at the begining they are
obviously separate waves since you have represented them with separate input
values, and given a linear transfer function for your point on the wire, or
in space, they can always be kept separate. it is only your act of

calculating the power at that point that combines them.

Tom,

For most purposes the terms superposition and linearity are
interchangeable. However, for the purists there is a difference.

A system that is deemed linear requires that it has the properties of
both superposition and scalability. These properties are essentially the
same for simple systems, but they are not necessarily the same when
considering complex values. I found some clear examples in a book, "The
Science of Radio", by Paul Nahin.

One example, y(t)=Re{x(t)} describes a system which obeys superposition,
but not scaling. Hint: try a scaling factor of "j". That system is not
linear.

Another example is y(t)=[1/x(t)]*[dx/dt]^2. That system obeys scaling,
but not superposition. Again, it is not linear.

The bottom line is that superposition is necessary, but not sufficient
to ensure linearity.

You are correct that the definitional issue is not relevant to the
current RRAA discussion.

If a probe is confined to the null
"space" consisting of the plane between
the antennas, it seems clear it cannot
distinguish between radiation from the
two antennas.

But no probe so constrained can detect
radiation from either antenna alone (or
from any other radiating source).

Seems somewhat tautological then that
the probe cannot be designed to
distinguish between the two antennas.

If the assumption so constrains the
probe to fatal infirmities under any
circumstances, then the observance of
failure in a particular circumstance is
void of information.

No?

Chuck

If V^2/Z0 and I^2*R cannot be reverse superposed
in reality, doesn't that imply than neither can V
and I be reverse superposed in reality?

Doesn't a real world EM wave require ExB joules/sec
for it to exist and to have an associated voltage
and current?

Should work fine. I know a fellow who put a wire on the end.

Just which frequencies you'll cover will vary, though.

True, but we also know that the power is zero at every point
between the Z0-match and the source. That gives us an
infinite number of points with which to work and we still
cannot reverse superpose the two original superposed waves.

Your highly technical rebuttal of my posting is noted.
Have you ever seen the equation?

The integral of e to the x = function of u to the n

```
__
|_
__|e^x = F(u^n)
```

hi
they say that when a radio wave hits a reflective surface and bounces
back it under goes a 180 degrees phase shift .

1,what exactly is the reason for this phase change, is it because of
the change in direction or any thing else.

2,does this phase shift of 180 degrees mean a shift in polarity(ie
from +ve to -ve and vice versa)

Google can be your friend. Please learn to use it. One thing I'd add to the paragraph below is that the metal creates what's commonly called a "boundary condition." In this case, it enforces the electric field in the metal to be (essentially) zero...which means that right next to the metal surface, whatever electric field there is must be perpendicular to the metal. That will/can help you understand the "angle of incidence equals angle of reflection" thing. Rather than typing in a similar answer, here's something that looks pretty good from www.physicsforums.com:

"Specular (mirror) reflection by metals of electromagnetic (EM) waves, including light, is not a quantum process. There are not absorbed and reemitted photons.
An EM wave has an alternating electric field that oscillates at the frequency of the wave. The limit condition of electric fields and perfect conductors is that the electric field in the perfect conductor must be zero. If not, the current should be infinite.
When free electrons in a metal "feel" an alternating electric field, they began to oscillate at the same frequency as the field. An oscillating electron radiates an EM wave polarized in the direction of its movement. That is, with the electric field parallel to the movement. This EM wave is radiates in all directions, with a maximum in the plane perpendicular to movement and a zero in the direction of movement.
In a perfect conductor, the amplitude of the emitted EM wave is identical to the incident wave. In a real metal the emitted wave is slightly smaller than the incident one.
The phase of the emitted EM wave is such that at the metal surface and in the metal side, the addition of the two waves is zero. In the incident wave side the two waves travel in opposite directions. Seen from outside one has the impression that the wave coming from the metal is the reflection of the incoming wave. It has the same frequency and amplitude. But, in reality, it is a wave that has been emitted by the metal electrons.

When the electric field is parallel to the surface of the mirror, the reemitted wave has the same polarization. When it is not the case the polarization of the reemitted wave is a little trickier.
There is not need of metals to obtain a "metallic" reflection: free electrons suffice. There are a lot of them in the ionospheric plasma. The ionosphere reflects radio waves at low radio frequencies (under a few MHz). And some metals can be transparent to light. The potassium is transparent to near UV.
Real metals are not perfect and their conductivity is frequency dependant. But except copper and gold, they reflect fairly uniformly in the visible band."

Thanks, Gene--those examples are helpful. I'll retract what I posted last night.

Based on the "necessary but not sufficient" statement above, we can say that superposition does hold in a linear system, so if we specify a linear system, we do have that guarantee.

Cheers,
Tom

Gene, I've got an experiment for you. Go to:

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

and set one phase to 0 and the other phase to 180 degrees.
Then get an index card and cover up everything to the
left except one point on each wave. All you see is those
two single points moving up and down. That gives you a
visual idea of how s11(a1) and s12(a2) originate and are
canceled at a Z0-match *point*. Plot those points back
in time and you will have a history of the canceled waves
from which you can compute average power density as
|s11(a1)|^2 and |s12(a2|^2.

4903. Lengths of radials for Diamond X-3200A

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-21 20:13:25 UTC
From: "Rick (W-A-one-R-K-T)" <get.my.email@from.qrz.com>
Message-ID: <pan.2007.04.21.20.13.24.337527@from.qrz.com>
Source record: 42401

I seem to have lost the radials for my Diamond X-3200A 144/220/440 triband vertical, and so I'm going to have to make some more.

Can anyone tell me what the length of the radials is supposed to be?

I'm guessing 19" but it seemed to me they were shorter than that.

Thanks...

> observation point of 1/16 lambda.

Someone has said that the formula I gave is not valid for a phased array.

His comment (about the 2 D^2/lambda) is below:

That estimation does not apply in this case. It can be considered to be
valid for aperture antennas which is not the case here. It would only
require to have the transmitting antenna illuminating the pleased array
within its 3dB mainlobe which of course is by far the case at a distance
of 3000m or even more.

I'm not to bothered about the odd factor of two. I have seen a
derivation of the formula, but it was based on a rectangular aperture,
not an array of them. It don't know if that may mean the equation is
just not appropriate at all.

Using that forumal puts the far-field distance at about 10 km in my
case. Using someone elses idea, puts it at only a few hundred meters.
There is at least a factor of 10 difference.

Hi all again

W4ZCB emailed me about this, but my attempts to reply have failed.
Anyway, W4ZCB suggested his paper, which has a nice physical (non
mathematical) explanation of the far field.

http://www.setileague.org/articles/hps_ham.htm
http://www.setileague.org/articles/ham/farfield.pdf

Unfortunately, it does not solve my particular problem.

Cecil,

You are going to pull a brain muscle by stretching so much. Are you suggesting that two wiggling points on a web page are the key to understanding the universe?

Here's a thought experiment for you. Read the message by Tom, K7ITM, where he copied a quote from physicsforums.com. See if you can figure out how those waves you insist are created and then quickly canceled (delta-t later) might have never existed in the first place. Hint: waves don't interact with each other, but they do interact with materials containing electrons. (I believe that covers quite a few materials.)

73,
Gene

This sounds very much like an arrangement for a radar antenna that
operates a little above 1Ghz with 32 dipole assemblies space out over
approximately 10 meters. The far field is eatablished at about 2km on

this antenna.

Its been a long time since I did any 4 wheeling but I had the same problem back in the 70s and found that replacing the stock antenna with a 4 ft fiberglass top loaded CB antenna worked great. Seems like back then they had a mount just for doing this that replaced the factory antenna. Dont know if you can still get one or not. My nephew does this sort of thing and after replacing a couple of CD players he keeps all his music on an iPOD and plugs it into his broken CD player.

No, it is not that at all, but if you have a reference to the antenna
you describe, I would be interested. This is wider and a higher frequency.

The antenna I was refering to is knon as an ATCRBS antenna or an SSR
antenna. I coouldnt find a lot of info right off but there were a lot
of references t oIEEE xplorer. If you belong to that Im sure you can
find some information.

Like chess? send me an email and I will connect you will a friend who
has been known to give a challenging game or two.

It was Gauss who started a progression from statics to
electromagnetics by defining a clustered array as being in equilibrium
within a closed surface in his law of statics
Nobody used this law in the design of a electromagnetic array. There
were mathematical
equations in existance that linked statics and electromagnetic
functions in mathematical terms but there was never a clue as to how
to demonstrate it. Only Gauss gave an "at rest" example of such an
array with his law of statics but even he did not continue with his
line of thought with respect to static particles as being at rest on a
radiating array where the condition of equilibrium could be stated. If
Gauss had continued with his line of thought by being aware of
radiation in terms of radio I am quite sure he would have continued
the exercise with the addition of time. However it is my understanding

that at that time he was residing in Italy and was more interested in other things. I do not recall Gauss, Maxwell and other masters making a point of using such a cluster as one of maximum efficiency with respect to radiation. Nor do I recall any mention where scientists have used such an example in print and either lauding or decrying its properties in the light that the ratio of elements vs boom length does not apply and where a Gaussian array was an example of a non scalar array. I am sure that it is possible after the event that many clever people played with such arrays and like you decided it wasn't worth writing about and so forgot about it.
There are also people who never linked the subject of statics with the subject of antennas
as mentioned on this newsgroup and I don't remember seeing such an array in Krauss and Jasik or even the ARRL antenna books which to me is a real puzzle since you apparently have known about the hints that Gauss supplied for maximum efficiency radiating arrays for many years. So I think the time has come since I have described the antenna in detail that somebody should come forward and share with all exactly where this application to antennas was reviewed in print or the IEEE or equivalent so that we can all benefit from this peer review.

4917. HF vertical

Have recently rcvd a very old HF vertical antenna. It has 4 traps of various lengths and overall lenth is about 30-33 feet total. Cannot figure out what brand it is. Donor has no clue. It also has rings on several separators for guy lines. I thought it was an old Hygain, but nothing in their current catalog looks like it. Best guess is that this antenna is about 35-40 yrs old and even wonder if it's worth the effort to try to assemble as it is in parts and there were no instructions. Found out from donor that it was only used as a listener, i.e. never was transmitted on... Making me even more suspicious of its reliability to use!
Any one with any ideas/thoughts---would be greatly appreciated!!

Hmmmmmmmmmm. Sorry about the one way skip, my ISP apparently doesn't like your ISP. Happens occasionally. Glad you found Pauls article, was going to be a bear for me to scan it for about the 10th time.

So, I give up, what IS your particular problem? As stated, the far field depends on the antenna gain.

Source record: 42418

All,

As many of you may recall I have been trying measure and improve a loaded vertical on 80 meters. The antenna is permanently mounted on a radial field. The issue has been measuring and improving the performance of that system. The predicted values are for the antenna element to have a low impedance in the range of 6 to 10 Ohms. The ground is added to a total impedance of 48 to 54 Ohms, depending on moisture.

As part of that process to determine the actual measurements I created a 2 meter model. The element is a loaded vertical from the ARRL handbook. The ground is set of shortened radials. That antenna measured a reflected power of 6.9 db at resonance. This calculates to an antenna system impedance of about 18 Ohms. This is the range of the answer I was looking for in the 80 meter antenna.

This is a good result. It confirms the range of predicted values for a loaded vertical. The next step is to measure the actual 80 meter antenna. That will result is a good ground measurement and support ground a radial system.

Hi Art,

An Italian by the name of Marconi was interested in exactly those kind of things. Other Italians by the Bellini and Tosi designed sloping elements fed by what by description would be called a goniometer. By adjusting the coupling of coils they could send/receive signals at any angle. This was all going on nearly 100 years ago.

Coils, Gauss. Sloping elements, clusters. Any angle, through coupling. Sound familiar?

>somebody should come forward and share with all exactly

There was no such thing as the IEEE back then. Before the IEEE it was the IRE. There was no such thing as the IRE back then either. Before the IRE there were Ham magazines. There was no such thing as Ham radio back then either. Marconi won the Nobel prize in Physics for this 98 years ago. His peers were Nobel Laureates. You want publications? Try the Nobel Lectures, Physics 1901-1921, Elsevier Publishing Company, Amsterdam. If you can read Italian, then Bellini and Tosi's work is available there too. English translations abound on the Internet.

Hi Dave,

Whether or not the formula is applicable, depends on many factors as mentioned in my previous posting.

For a broadside array, the formula holds with same accuracy as for continuous aperture antennas. In my antenna courses I use the

broadside array approach to derive the 2B^2/lambda formula.

For an end-fire case, the situation is different. When you are interested in main lobe gain only (so not the complete radiation pattern), you can reduce the distance significantly. The reason for that is that when you come closer to the antenna, the path difference doesn't change; the amplitude contribution of each array element is of importance now. However when you need to know the complete pattern (including broadside directions), you need the large distance.

It is just a matter of change in path length difference amplitude unbalance when you come too close to the antenna. If you keep this in mind, you can figure out the measuring distance for you application (for example with a spread sheet).

I would reserve the term "far field distance" for that distance where the complete radiation pattern does not change with measuring distance. In that case, the 2B^2/lambda formula is a good rule of thumb.

Best regards,

Wim

> 2,does this phase shift of 180 degrees mean a shift in polarity(ie
> from +ve to -ve and vice versa)

Hi Suresh,

Whether 180 degrees phase shift occurs, depends on the properties of the reflector, the frequency and angle of incidence. Phase shift does no mean change in polarization.

When you really want to know it all, search for "fresnel(l) equations" or take a physics book on Electro Magnetics. A related issue is "(pseudo) Brewster angle".

Keep in mind that physic books refer "angle of incidence" with respect to the normal of the reflecting plane and radio engineers many times use elevation angle as angle of incidence. Also when radio engineers speak of "vertical polarized" wave reflection on earth's surface, physicists do speak of "parallel polarization". They call "horizontal polarization", "normal polarization".

Best regards,

Wim

> is an instantaneous zero energy point every 1/2WL in an EM
> traveling wave.

Actually I said a zero power point, but you are essentially
correct. If the zero power point is stationary then no energy
can be flowing. When energy is flowing, either there is no
zero power point, or the zero power point is moving as well.

At a given point on the line, when the voltage or current is
always zero then no energy is flowing. When energy is
flowing, the voltage and current will not always be zero at
that point.

There can also be a voltage and current but they can be
90 degrees out of phase so no net energy flows. In this
case, energy will flow first forward then backwards with
an average of zero.

My situation is very odd. As I said at the start, this is not an amateur antenna.

The array of "antennas" are not designed to work as one nice antennas, but are an essentially random(ish) collection of radiating centres. (However, they are all energised from the same signal source). So they can be considered like a phased array, as they are regularly spaced all in one long line.

Hence my original diagram

A---A---A---A---A---A---A---A---A---A

accurately describes the situation. Each "A" is an antenna. The amplitude and phase can be arbitrary.

I do *not* want them to behave as a nice phased array with decent gain and low side-lobes! Each antennas is radiating an *unwanted* signal. But the fact remains that the gain could conceivably be high under some circumstances, which would create interference.

Hence I need to test this.

> I would reserve the term "far field distance" for that distance where

In this case, I am interested in any direction. The direction of the main lobe will be essentially random.

it probably hasn't been because nobody has bothered to write a reviewable paper on it... why don't you work on that and get back to us when you get it through peer review and it gets published.

So you expect that some of the reverse wave is reflected at the
generator and yet experiment has shown that none of the
reverse wave is reflected at the generator when the generator]
source impedance is the same as the line characteristic
impedance. I am curious as to why you ignore these
experimental results.

> in its tracks.

As you noted previously, it does not matter whether the
reverse wave is created by a reflection or another generator.
So the experiment has been done with a generator at both
ends of the line and the results are entirely consistent with
the results predicted using the generator source impedance

to compute the amount of reflection. I am curious as to
why you ignore these results.

And, of course, there results are consistent with the analysis
described in any basic text book on transmission lines.

Hi Dave

I'm curious about two things.

1 - Do you intend to actually make and record measurements of the radiated field, or do you want to determine the minimum distance at which the measurements can be made?
2 - What prevents the use of a computer modeling program to predict the pattern?

Jerry

yes

nothing. I think that will be done. But a theoetical analysis would be
nice if possible.

[all text deleted]

Hi Dave,

I don't know what you are going to do with the array. As long as you
understand how a radiation pattern (whether within or outside the far
field distance) can be calculated based on the array elements, you

should be able to find a comfortable distance. I think references to scientific documents will not help you any further, maybe a physics book on electromagnetism or a specialized book on beam forming antennas may help you.

If your organization is not able to do this in-house, you might hire an expert.

Best regards,

Wim

No David, if people were aware of it there would be endless books
about it. Think about what this newsgroup has said. If you have a
mathematical equation you cannot add the unit of time to BOTH sides of
that equation! How dumb can you get and these people view themselves
as antenna experts who demand mathematical proof. David my intent is
to expose them for what they are. Look at what Richard stated in
response to my posting, you have to dig a bit and then take a guess at
what he is talking about but he mentions "coupling" as being the meat
of his reply. But most people are aware that if an array is in
equilibrium then there is no coupling ! Coupling with respect to
antennas the subject at hand requires elements to attract or deflect
such it allows for focussing of radiation.Equilibrium is a state where
such actions do not exist. Another person gets irate because the terms
polarity and polarization were used in a single posting regarding

antennas since one of these terms he had a disliking for(I don't know which one). And then there was that hulla balloo about the introduction of statics in connection with kinetic and potential energy as if that was sacrelidge . Then there was that time when all stated that the Yagi was a most efficient radiator when they pushed aside the notion that interaction between elements was not a measure of inefficiency. They also went into denial that a cluster in equilibrium presented the ultimate in efficiency as coupling did not exist.And it goes on and on David. And the more they talk the more they expose themselves for what they are. What I am doing by staying on subject is laborious to say the least but when posters retrieve all the writings about potential and kinetic energy by Maxwell that many ignored including Terman and many others but they knew about all along will all come out
to the amateur fraternity and they will be exposed. That is my aim in what I do and when my writings are published it will be there for all to see that contrary rationilisation by this group is generally a bunch of hooey by illiterates and the sole reason why accepted experts in the field of antennas are noticable by their absence.

Waves pass thru each other without interaction!
If intra action occurred then multiple radio conversations at the same
time could not occur.
Why 50 odd posts to state the obvious?

unfortunately much of engineering requires equations. if you can't write
the equations well enough to explain the concept then you are going to have
a hard time selling it to the engineering community. you may be able to
convince some lay people that you have a new concept, like the EH and other
'new concept' charlatans have, but in the long run it won't fly.

Hi Dave,

As I've already pointed out, this was done a long time ago and is in
the library.

20 years after that work, better designs came down the pike - namely
the Yagi. How many folks are writing "reviewable papers" about that
design? Not many since Isbell some nearly 50 years ago.

The equations were explained quite well by Dr John Davis some time ago
on this newsgroup.
Some even say that they knew about this all along! Some are not
interested in anything only in aurgueing. David this newsgroup is
about antennas and radiation, virtual this orimaginary that is for
people that just want to argue. Just look at the simple dipole where
we cannot accept it being efficient other than at 90 degree multiples.
Engineers look at a vectorial reconstruction of radiation and find
that the resultant vector is not and cannot be inline and parallel to
the radiator itself ,so they decide to ignor the fact and move on to
another subject.
You would think that a group of engineers would be interested in why
in the world would we not be interested in the final vectors
characteristics such as to where it was pointing!
You would also think that engineers would be interested in antenna

design which by not involving interaction such as focussing does not produce side lobes or provides bandwidth characteristics that are in synch with each other but no the interest lies more in trying to kill the messenger where true engineers are trying to build on this information given and present it in their good time. The fact is that Maxwell stated many years ago the interconnective aspect and I gave an extension to Gaussian law that expounds on an array in equilibrium which shows simplicity at it's best what Maxwell enunciated. Nowhere is there writings with samples of the simplicity of this arrangement in the multiplicity of radiation books available
and since the majority are not capable of individual thought that they have to await the printing of a more modern book which they can point to for reference. Remember Gausses law was based on static particles at rest not caring one iota upon the dormant parts on what they are resting on or part of by describing them being in a state of equilibrium with a state of potential energy. It is for engineers to review a transition from potential energy to kinetic energy of these particles where when time is removed the initial equation still stands. This I have provided an example which existing antenna computing programs concurr with. In addition the sample describes the near field as being a separate entity to its self and where the radiation field does not begin within the confines of the radiator itself where coupling interferes with the separation of potential energy and kinetic energy formation.
Best regards
Art

Hi Dave

Would you consider building a scale model of this array to allow a polar
orbiting satellite to be the illuminator?
I get some pretty good radiation pattern plots at VHF, using Patrik Tast's
SignalPlotter program and NOAA satellites.

Art Unwin wrote:
"It was Gauss who started a progression from statics to
eletromagnetics by defining a clustered array as being in equilibrium
within a closed surface in his law of equilibrium.

Clustered array rings a bell! Is clustered array Art`s idea of a
Gaussian antenna?

J.D. Kraus wrote on page 185 of his 3rd edition of "Antennas" (a must
have):

"I delved into a monumental treatise on "Directional Antennas" by George
H. Brown of RCA. Buried deep in the article was, to me, an astonishing
calculation which indicated that parallel linear dipoles with spacings
of 0.125 wavelengths or less had higher gains than customary larger
spacings."

Terman in his 1955 opus gives the caveat, on page 906:

"A characteristic of all close-spaced arrays is that as the ratio of
size to antenna gain is reduced, the radiation resistance also goes
down---. The result is a practical limit to the amount of gain that can
be achieved in a compact antenna system, since as the resistance goes
down the fraction of the total power dissipated in the antenna loss goes
up. The Yagi antenna of Fig. 12-39, and the corner reflector, represent
about the best that can be achieved in a practical way with respect to
directive gain in a compact antenna array."

True today as it was more than 50 years ago.

Best regards, Richard Harrison, KB5WZI

It's not really practical to do that for various reasons. The structure
is not a nice conventional antenna that can be scaled up/down size.

That's a concept I have not heard of before. But for me to work at VHF,
I'd need to make the structure larger by a factor of 10, so it would be
several hundred metres long.

Hi Dave

You are not restricted to VHF. It is possible that there is a polar
orbiting satellite transmitting continuously on the frequency you are
interested in. NOAA satellites transmit continuously at about half the
frequency range you refer to.

Richard you should be able to do better than that! A cluster does not
have to have a dimensional reference such as element spacings, It is a
random arangement of parts, that is any parts, not just radiating
elements. Have you heard about cancer clusters and the like?.

And he was incorrect with respect to spacings and parallelism and
maximum gain. His observations were purely within the confines of
radiating arrays with parasitic elements only and has nothing to do
with non parasitic arrays. Again Richard you are taking things out of
context since the arrays refered to were not in equilibrium. Period.
Is it possible he can come back to life and write a third volume so
that he can put into todays perspective what many achieved after his
demise that he knew all about before he died? Or are you implying
that nothing new has been found with respect to antennas after he died
by your own personal experience?

Again Richard you are taking things out of context! And frankly you
are doing it more in an accelerating fashion when compared to your
age.. Terman is refering to close spaced arrays of the parasitic form,
even mentions corner reflectors. Termans phrase of practical
gain is a term often used in the design of parasitic arrays where
practical versus theoretical cannot be attained. Nowhere does Terman
acknoweledge the name of Maxwell,Lorenz e.t.c. in his writings
completly ignoring their contributions in a measure of self
angrandizement.
If he had acknoweledged the works of Gauss he may well as arrived at
arrays in equilibrium
but he could not or would not acknoweledge the works of the masters,
probably because they were European.
Within the envelope of his personal knoweledge what he said 50 years
ago was and is true to those who deny todays advances of science.You
cannot hold on to verbal tails of yesteryear in an effort to impress
those who are skilled in the present day state of the art. Did Terman
discuss satelittes, wifi, the impact of Einstein with respect to
antennas or potential momentum? Ofcourse not, he was not aware of them
because he was of an older generation and his books contain lot of
stuff that is completely out of date in line with cave mans readings.
>

> True today as it was more than 50 years ago.

It just amazes me how you old timers reach back to their school days
and books used in an effort to elevate their own generation by quoting
old books as the testimony that all is known about antennas. This is
akin to sayingt that by their own experience the teachings of Terman
was all encompasing which they themselves could not improve apon which
is very plausable considering the deteriation of brain power of the
constituent members. If you relied on memory instead of personal
thought in you exam days then it becomes obvious that your
position in scientific life will descend faster than you age. If you
are going to continue quoting the written word it is critical that you
write down what the subject matter is so that you don't forget it and
get confused.

the only antenna with particles at rest is one that isn't transmitting or
receiving... not much use in my opinion.

Put it up and check it out you may luck out. If not remove all the traps and put a tapped loading coil on the bottom so you can tune it to your favorite band. I know of 1 guy that had bad traps so he took them out rplacing them with fiberglass rods. When he wants to change bands he tilts it over and connects jumpers across the fiberglass sections.

Richard you lie so often that are getting very fluent with your
imagination. I often laugh when you tried to suggest that you put the
Dr straight regarding mathematics. Also when you suggested that you
knew about gaussian antennas long ago but you are a bit confused about
whether you thought you launched the idea yourself or you saw
something written about it but with your flowery writing you have been
unable to communicate its actual origins. I also laugh at your attempt
to apply for a patent! Nothing like the patents written by Edison on
the back of a napkin. You wrote in your normal flowery language so the
examiner would be confused about what you were claiming, and like the
nose of pinochio your patent grew and grew and grew in size the
examiners sent it to Field and Stream thinking it applied in some way
to weed aplications.
Ofcourse it got back to the patent office and as you said it was to
big and volumous to fit into any enclosure the PTO had on hand and as
you said they put in on the floor where it gathered dust because the
examiner couldn't or didn't want to find it. Tell the group what that
patent number was so they can read it for themselves tho you never did
say if a patent was granted and whether the title was clear enough so
it could be placed into the correct category. Richard you are in a
imaginary world when you say you believe, think,know, that a
dissertation on Gaussian arrays has already been written when most
realise when reading your posts you have no idea what the concept is
about in the first place so you will never ever be able to recall the
underpinnings for what you are claiming credit for. So really it will
be no different to the many other things you have said or claimed
because your prose concealed all so succesfully. Richard you are the
Andy Cap of the antenna world and pretty good at it I might say.

> pattern of the antenna? Just curious...

Yes. The "counterpoise" is just as much a part of the antenna as the "antenna". Giving it that label doesn't prevent it from radiating or interacting with the antenna. The wire from the base of the antenna to the "counterpoise" wire is also part of the antenna and will radiate. The presence of the lossy ground will reduce the effect that the "counterpoise" wire direction has, but it will still have an effect.

You can find out just how much an effect it will have by using one of the readily available modeling programs. The free EZNEC demo available from http://eznec.com would be adequate to get a fair idea.

Art wrote:
"Again, Richard you are taking things out of context since the arrays referred to were not in equilibrium.'

I noted no acceleration nor motion. As a firm believer in the conservation of energy I`m sure that the antenna, on average, received no more energy than it emitted or conducted away. That is balance or equilibrium.

Art also wrote:
"Terman was referring to close spaced of the parasitic form, even mentions corner reflectors."

Yes, and he also mentions the Yagi array. But I believe Terman meant to say the best antenna gains of the day, for the antenna`s size, regardless of direct or parasitic drive, were obtained from corner reflector and Yagi antennas. That hasn`t changed but it certainly may. But, Kraus, whose invention, the W8JK array, has two dipole elements spaced 0.125 wavelengths apart and driven 180-degrees out of phase, certainly has no parasitic element. That was certainly on his mind when he wrote the comments on page 185 in "Antennas". On the facing page, 184, he diagrams two antennas, the W8JK and a stack of two dipoles which are driven in-phase, not out-of phase like the W8JK.

Low radiation resistance is a consequence of tight coupling between the closely-spaced elements. This makes the coupling to the array likely lossy in making impedance transformations necessary to match the array to the transmission line. Kraus has some suggestions on how to make these arrays more compatible with their transmission lines.

Best regards, Richard Harrison, KB5WZI

So he didn't say what you think he meant to say.......hmmm!

the best antenna gains of the day,
could be, he wasn't aware of Gaussian arrays was he?

for the antenna`s size,
> regardless of direct or parasitic drive, were obtained from corner
> reflector and Yagi antennas. That hasn`t changed but it certainly may.
Let me assure you it has changed much as you want to bresist change.

If both dipoles were separate entities where only one was driven and
both entities
were resonant then it is representitive of a Gaussian array assuming
both elements were not parallel or planar. I will leave you to decide
if it was an example of a Gaussian array.

>
> Low radiation resistance is a consequence of tight coupling between the

This is a statement connected to Yagi's or similar type parasitic
arrays
Are you like Terman who meant to say something different? How can you
be a mind reader
if you do the same thing yourself?

Kraus has some suggestions on how to make
> these arrays more compatible with their transmission lines.

That's nice. What am I suppose to do with that statement? Did you
intend to say something else like it was true 50 years ago so it is
also true now?

Jimmie you may reach the same age as Richard(you are nearly 80 years old aren't you) so you better start thinking ahead. There are different types of institutions you know and who knows what type you are assigned to.

No, just wave cancellation. If the graphic is completely
incorrect, as you say, why did they publish it?

Time for you to review EM waves, Keith. There is a zero
power point in every EM traveling wave every 1/2WL where
the E-field and H-field are both zero at the same time.

This from the person who used standing-wave current to
measure the phase shift through a loading coil knowing
all the while that standing-wave current has an
unvarying phase. I cannot think of any worse junk
science than trying to hoodwink the uninitiated.

I believe this to be untrue.
If an array is in equilibrium you have skin depth that give you a
resistance figure as well as d.c. resistance . You also know power
input thus all input and output power is therefore known. Pray tell
what energy cannot be accounted for?
Remember radiation does not begin to occur until the arbitary border
is punctured thus at that time it can be considered as output.
Movement of flux cannot begin until the clock starts
or time begins So now you have a beginning. An enclosed arbitary
border that containes energy and a end section that represents
radiation. You could also use the potential momentum theorem to
determine the exit proportions of electric and magnetic particles to
generate a electromagnetic field as well determining what particles
return to the radiator to serve in the formation of skin depth or
radiation resistance which serves to augument time changing current as
well as accounting for decay. All this requires a smattering of
understanding with respect to Einstein law of relativity which most
will probably tend to dismiss as hog wash especially those who view
the subject of static particles as being useless.
The answer Roy gave is only applicable when an array has parasitics
that either deflect or attract energy with respect to polarity(Walter
note the use of the word "polarity" with respect to antennas)
Ofcourse some will drop back to point out Pointings Vector so this
could be interesting.
If you want to disagree start off with a resonant dipole to ensure
applicability of ones auguments.

Hi Art,

I bought a Goniometer at my first Ham auction in 1966. Only 41 years ago, but it was only 50 years old then (the concept, not the goniometer), and now the topic has been around for so long that most have forgotten it like the sand that surrounds the Sphinx.

Can you explain how the Goniometer, the conceptual child of Bennetti and Tosi?

Chances are it is 40-80 meters. First set it up with the smallest
trap near bottom and have them get larger as they go up, if you
haven't done so already.

Then test for 10 meters. If there is a decent match, fine tune it by
adjusting the lower trap up or down until it is good. Next, 15
meters, then 20 meters, then 40 meters with the top of the pole.

As someone else said, you may get luck with the first shot.

Not what I am implying at all, that wouldnt be funny. I only wish I knew as much about antennas as Richard.

I only recently obtained copies of books by Krauss and Terman and have begin to intensify my studies of the subject.

While on the subject, I obtained my first class FCC license in 73 and the material in Terman seems to fit very closly with the study material I had. Is there a connection between the test and Terman's book?

Tom ,you should not hit Jimmie for not studying what you believe to be critical. To often you have shown yourself to be ignorant of the finer details of radiation that you are accusing Jimmie of not being knoweledgable about. Regarding what Richard stated you did not give one iota of evidence that his comments were correct possibly because you are devoid of any knoweledge around which you could consider a debate. Tom once again you show your ignorance about antennas and radiation to the World. Wasn't it you who was so vociforace in your critisisms when the MIT doctor came aboard with his mathematical analysis? Was it not you who stated you cannot add the measure of time to both sides of an equation infering that equilibrium is thus abandoned? You really should have obtained an understanding of algebra before embarking on a realm of finger pointing at the old age of the mid eighties.
You can talk the talk when you prove that you can walk the walk and that can't be done if you have a crippled mind.

4968. Re: Measuring Antenna Efficiency

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-23 03:33:36 UTC
From: richardharrison@webtv.net
Message-ID: <10571-462C2910-810@storefull-3257.bay.webtv.net>
Source record: 42268

Jimmie D reported Roy Lewallen to write:
"There is no direct way to measure the total power being radiated other than sampling the field at many points in all directions and integrating."

That sounds right to me. An approximation is sometimes made by taking 36 samples of field strength in volts per meter at 10-fegrees of azimuth intervals at the same distance from the central antenna system. Each of these sample values is squared and the sum of these squared samples is divided by 36, the number of samples, to get their average. The square poot of this quotient is then the average field strength at that distance from the antenna. A true average signal strength should be the same as the value an isotropic antenna would radiate at a given distance.

Knowing the field strength, one could calculate the watts per square meter of the envelope of radiation at a given distance and total the watts per square meter of all the squares to get the total power being radiated.

Since 1960, I`ve used the Bird wattmeter satisfactorily to get the total power being delivered by the transmitter and radiated by the antenna. It should be the same if the transmission line and antenna have low losses. It is simply the difference between the forward power indication and the reverse power indication. Many lines and antennas have very high efficiencies.

Best regards, Richard Harrison, KB5WZI

Cecil,

Four questions:

* Does your IEEE dictionary have an entry for "stationary"?

* Which part of "every EM traveling wave" is stationary?

* Do you actually read any of the messages to which you respond?

* Do you want to retract your answer?

Cecil,

I did not say the graphic was incorrect, but rather that it is

Is that true?

Firstly you seem to assume that your 36 samples around the azimut circle adequately fulfill Roy's "sampling the field at many points in all directions", surely he mean't all elevation angles as well as all azimuth angles.

Secondly, your suggestion that the average field strength (presumably for a 100% efficient antenna) at zero elevation is the same as for an isotropic antenna at the same distance seems to preclude the antenna having directivity in the elevation dimension.

No I wish I had had the book then, I took a course(before Bash) at the time
that also seemed to follow Terman. When I went up to Atlanta to take thes
test I only thought I was giong to take the parts for the second class
license and passed the test for first class also. I felt like I didnt know
my own name when I was finished and had no clue whether or not I had passed
even the second class portion. I really didnt believe I had. Funny thing is

I have never used the license. Stiil just skiming the books but Terman seems a little elementary now and Kraus is going to require me to bone up on my calculus, something else I havent used since 1979. Hell I dont even know why I am bothering, fine cooking and ballroom dancing are much more important to me now.

Owen,

These examples are quite different. Experiments in one cannot be used to make an inference in the other. One is electric flow, the other is photons. The physics are not even close to the same. Which one do you want to talk about?

- Dan

Electrons move in a conductor very slowly. Far, far, below the speed of
light.

So, when you put a voltage or a source of electrons (which have charge and
eminate their own tiny electric field) at one end of a conductor, what
exactly propagates through the conductor, so that the voltage at
the end of the conductor appears (i.e. becomes measurable) in a
time suggesting propagation of the voltage (or charge) at near light speed?

Charge.

Put a row of marbles or ball bearings on a table. Roll another one so it strikes the near end of the row, and notice that one leaves the far end very quickly. A unit of momentum (a rolling ball) hits the near end, and that unit of momentum propagates to the far end and appears in the form of a rolling ball there, much more quickly than the balls themselves roll. In this case, the momentum of the ball is propagating very quickly from one end to the other.

Similarly, a unit of charge (analogous to the momentum of the rolling ball) propagates much faster than the electrons. Put a unit of charge in one end, and a unit of charge pops out the other at near the speed of light, while the electrons themselves move at something like a few miles per hour.

Not only do electrons only move at a few miles per hour.
The electricity the power company makes us pay for is actually
alternating current. And that means that the same electrons are being
pushed into our house wiring, and then pulled out of it, over and over
again. And yet we have to pay as if the electricity were
new. Disgusing!

Did a radio test with a 10mW beeline transmitter. Put it up in a tree at 8' and had houses and car dealers in front of me. Lost reception with an aftermarket Diamond antenna on the H/T at .6mi. Bought some stuff at a large store like Walmart and put the homemade 7 Element beam on the H/T in the parking lot.Opened the squelch up and sure enough, I could readily discern the beeping and hear my callsign and voltage readings that were transmitted in Morse at 1.3 miles. Had a great F/B ratio so I could get a bearing. Works good for fringe stuff. Have a loop for closer in bearing determinations.

Kurt

Electrons DO move quickly in a conductor
but most of that motion is in random
directions. Electron drift, the motion
of particular electrons from one end of
a conductor to the other, is slow as
described.

FWIW, for most AC appliances and their
conductors, electron drift may be so
slow that electrons entering one side of
the plug never reach the other side
before a polarity reversal of the AC.

Chuck

Gene Fuller wrote:
> * Does your IEEE dictionary have an entry for "stationary"?

I'm afraid you have been taken in by my devil's
advocate argument based on Keith's faulty concepts.
If what he says is true about standing waves, then
the same concepts apply to traveling waves. If there
are no traveling wave energy components being transferred
when two traveling waves are flowing in opposite
directions, then it logically follows that there can
be no traveling wave energy component being transferred
when one traveling wave is flowing in one direction.

The *NET* energy flow is zero in a standing wave.
But the component energy flow in the underlying EM
waves is alive and well and flowing right through
those current and voltage nodes without even knowing
that they are there. The illusion of zero energy flow
in EM traveling waves is one of the problems with
shortcuts. EM waves have a set of boundary conditions
that must be satisfied for them to exist. One of
those conditions is that they must necessarily
travel at c(VF). "Stationary" is not possible for
any single EM wave. Nobody has been able to provide
an example of a standing wave without the underlying
forward and reverse EM traveling wave components
(not even you) :-). Another condition for the existence
of an EM traveling wave is that it has an associated
energy level without which it cannot exist.

A stationary EM wave is a contradiction in terms,
an oxymoron. EM waves cannot stand still
and exist only as a concept in the human mind.
It is an illusionary temporarily superposed profile
of two waves that, in reality, are moving in opposite
directions at c(VF) and have absolutely *NO* effect on
each other. The forward EM wave possesses direction
and momentum that doesn't change until it encounters
a physical impedance discontinuity. The reverse EM
wave possesses direction and momentum that doesn't
change until it encounters a physical impedance
discontinuity. Anything else would violate the laws
of physics.

OK, if it is irrelevant, why did they publish it?
Why do they talk about "redistribution" of energy
in other directions during a destructive interference
event? Doesn't changing the direction and momentum of
a wave qualify as "interaction"?

And when those two sine waves are coherent, of equal
amplitude, and opposite phase, they permanently *CANCEL*
each other. Doesn't that satisfy the definition of
"interacting"?

I see you have been strangely silent on my example of
s11(a1) originating and flowing away from the impedance
discontinuity only to be canceled by s12(a2) when it
flows through the impedance discontinuity and encounters
the s11(a1) wave flowing away from the impedance
discontinuity. How can the effect of one wave on the
other not be interaction when both are flowing away
from the impedance discontinuity and are *NEVER*
incident upon any impedance discontinuity?

So a CB antenna will work with AM/FM as well? I'm already running a
CB with a 4' antenna - any chance I could use some sort of splitter
and have that one antenna serve both the CB and the AM/FM radio, or
will that screw something up?

> want to talk about?

Current flow in lumped circuits is assumed to take
place instantaneously, i.e. faster than light speed.
In a DC steady-state, there is no acceleration of
carriers and therefore, no photonic particle flow so
the above shortcut works in that case. It doesn't
work in RF distributed networks where photon generation
and absorption never ceases. One of the boundary
conditions for EM wave flow is that is can never exceed
the speed of light c(VF).

One needs to know when one's model has become invalid
for the task at hand.

> per hour.

That works for DC steady-state. For DC transient-state, photons come into play because the electrons have been accelerated by the DC leading-edge step function. The DC impulse during the transient-state is photonic energy in action, i.e. electromagnetic wave action.

When a DC impulse is first applied to a transmission line, the ratio of its E-field to H-field is fixed at Z0 indicating that the energy transfer is photonic. During DC steady-state the ratio of its E-field to H-field is fixed by the load indicating that the energy transfer is electronic.

For EM waves in free space or in a transmission line, photonic generation and absorption never ceases because the electrons are being continually accelerated and decelerated. The cloud of photons is what transfers most of the energy and the electronic analogy breaks down.

It is a mistake to use a DC steady-state analogy for EM waves. EM waves must obey a strict set of boundary conditions including a ratio of E-field to H-field that always depends upon the medium.

EM waves cannot stand still. They must necessarily move
at the speed of light, c(VF). The illusion of a stationary
EM wave is actually two EM waves moving in opposite directions
at the speed of light. Both waves include all of the boundary
conditions necessary for EM waves to exist.

Again, if you can present an example of an EM standing wave
devoid of the forward and reverse traveling wave components,
now would be a good time.

Cecil,

Nobody said the "wave" was stationary, only the point of zero energy is stationary. You have again demonstrated that you are not reading and understanding.

The *NET* paragraph above is simply unmitigated nonsense. It appears that mistaken notion is one of the root causes of your continuing confusion. Until you get over this bogus idea of colliding energy flows there is no hope for further enlightenment.

Cecil,

I did respond to your example. I referred you to the message from K7ITM.
The answer is contained in his quote. Since you seemed to have missed
that one, here is the conclusion.

The waves you are trying to create and then quickly cancel, in delta-t,
simply never existed. Problem solved.

An interesting problem. What you're presumably trying to do is determine how far do I need to be to bound the uncertainty on a measurement in an arbitrary direction. Or, another way, at what distance is the collective effects of the phase error for each of the signals (due to path length differences) smaller than your measurement uncertainty (so you don't care anymore).

This can be quite challenging if you want to worry about -40dB nulls, for instance, because a very small phase error can result in a -40dB null becoming a -30 dB null.

Complicating it a bit is that what you're probably really concerned with is a statistical problem.. you've got multiple sources, a random direction of observation, (and practically speaking, some propagation uncertainties between antenna and observation point).

You might want to look for a paper by Dybdal and Ott: "Coherent RF Error Statistics", IEEE Trans MTT, v34,n12, Dec 86, pp1413-1420 which discusses this in some detail, and, as well, provides some nice approximations that are useful in practical systems.

One can come up with a "bound" for the performance from analytical means, and a Monte Carlo analysis can give you some statistics.

Owen wrote:
"Is that true?"

Only for limited conditions. Owen is correct that enough samples must be taken to catch all variations in signal strength, in elevation and azimuth if total radiated power is to be determined.

A simple vertical antenna rests on the earth and has a null at its tip. It is far from an isotropic radiator.

The sampling I described is done on AM broadcast antennas. Only the wave which travels along the earth is usually of any interest. The minimum distance from the broadcast antenna for any field strength measurements is usually one mile to be sure the far field is being measured.

The FCC`s ground wave intensity charts assume that if you have ground conductivity such as sea water, a certain power and antenna efficiency deliver 100 millivolts per meter at a distance of one mile from the antenna. Field intensity in millivolts declines linearly with distance so that at 10 miles you might have 10 mv/m if you have 100 mv/m at one mile.Power is proportional to the square of the voltage.

One can also use Ku-band DBS satellites as an illuminator.

HOWEVER, if you're looking for gnat's eyelash precision, watch out for
atmospheric irregularities/inhomogeneity dominating the measurement.
When you start to get to many km as your "distance to adequately
```

replicate plane wavefront" the propagation uncertainty will probably be the greatest source of error. You get "bubbles" of air with local variations on the scale of meters.

A more practical approach (depending on the precision required) is some form of near field measurement (or a measurement where the different path lengths from the radiator to the observation point are explicitly taken into account).

It becomes clear from your posts that you have a wave centric view of these behaviours. It is often valuable to have more than one way to view a situation. Let me offer you another.

While I will describe this view only for transmission lines, its equivalent in free space would be the Maxwell equations, so, knowing your support for Maxwell, you should find it attractive.

The voltages and currents on a transmission line can be described with a collection of differential equations. When these differential eqations are solved for a set of boundary conditions, the results describe the voltage and current on the line as a function of time and location along the line.

Were one to set up an ideal line (for simplicity), terminated in its characteristic impedance, the functions that describe the voltage and current on the line can be derived. Plugging in the time and location one can determine the voltage at that place and instance. The curious investigator will be tempted to plot the voltage for a particular time as a function of location. The resulting plot will be nicely sinusoidal. Were one to plot the result for deltaT later, one finds a plot with exactly the same shape, but slightly shifted. A movie would show this nice sinusoid shifting its location at a constant velocity. And our intrepid investigator names this a travelling wave, a convenient moniker.

Let us consider another line. This one is open circuited. Solving the diffential equations that describe the line for these new boundary conditions produces a different set of functions of time and location. Plotting the function of voltage with respect to location again produces a sinusoid, but the amplitude depends on the

selected time. This plot, when played as a movie, shows no sign of moving and our intrepid investigator names it a standing wave, another convenient moniker.

But just because they are both called waves does not make them the same. One always has the same shape and amplitude and appears to move. The other shares the shape, does not move and has an amplitude that varies. Fundamentally, they are both just convenient visualizations of solutions from the same set of differential equations with different boundary conditions.

For the standing wave, further arithmetic reveals that the function that expresses the voltage as a function of time and location can be simplified and made more useful if it is expressed in terms of two travelling waves, one from the left and one from the right. But this is just an alternate expression of the function that resulted from the solution of a set of differential equations.

While the initial differential equations express voltage and current, one could certainly derive equations that expressed power, or energy storage, or whatever happened to be of interest. One could then solve these and the expression that results would be a function of time and location.

Were one to solve the differential equation for power on the open circuited line at a location of a voltage null, the answer would be zero. And all computed without the need for forward and backward waves.

So which is the truth? The differential equations or the forward and backward waves? Which analysis technique is more complete? And which is the alternative view that makes the problems solvable in reasonable time?

It is clear to me that the differential equations rule, much as Maxwell's equations are considered the root for electric and magnetic fields.

Travelling and standing waves are mere visualizations, though that visualization simplifies solving many problems. But forward and reverse waves are definitely not the foundation on which all else rests.

...Keith

I think he may be too busy having that strange kind of dream he talked about when he implicitly threw out at least 90% of all S-parameter analysis by saying that "reality requires complete reflection of the return wave at the interface between the [matched] source and the line." Either you believe in the superposition principle in linear systems, or you don't. He obviously doesn't.

> there is no hope for further enlightenment.

If colliding energy doesn't flow, then waves interact
away from an impedance discontinuity since the colliding
energy components are in separate EM waves traveling in
opposite directions. Which will it be? You cannot have
it both ways.

1. The ExB joules/sec components in the forward wave and the
reflected wave pass through each other with no interaction
such that the *NET* energy flow is zero.

2. The ExB joules/sec components flowing in each direction
cause all energy to stop flowing because of wave interaction.

Please tell us which one is true and which one is false.

Problem solved by rendering an s-parameter analysis
invalid?

b1 = s11(a1) + s12(a2) = 0

So s11(a1) and s12(a2) in the s-parameter equations don't
exist and never existed. Don't you think you should tell
HP so they can change their Ap Notes?

The *NET* power at any point on a lossless stub is
zero so that is no big deal. The standing wave
current is always 90 degrees out of phase with
the standing wave current so cos(90) = 0. At a
voltage node, all of the energy has simply moved
into the magnetic field.

Calculate the number of electromagnetic joules in
the line and get back to us on how they are reflected
from your above purely virtual impedance at a
voltage "null" and how they can even exist without
a velocity of c(VF).

Superposition is known to fail in nonlinear systems.
A source is obviously not linear. The V/I of an active
dynamic source resists any attempt at linear
superposition. How does your superposition work
when you try to spit up a fire hose?

With 4 amps of RF current at that voltage "null",
how could zero joules/sec possibly exist at that
point? Methinks there are some I^2*Z0 joules/sec
in that 4 amps of RF EM current that necessarily
must be traveling at c(VF).

Sources are linear. Consider the classic voltage source.. it has zero impedance. You can stack as many voltage sources as you like, and the voltage at the top of the stack is the same as the sum of the individual voltages.

The V/I of an active
> dynamic source resists any attempt at linear
> superposition.

-> a practical RF source, perhaps, might be nonlinear, although it's pretty easy to come close.. Consider an oscillator isolated by an isolator or a big pad.

How does your superposition work
> when you try to spit up a fire hose?

Just fine. No different than receiving a faint signal superimposed on a large interfering signal at a different frequency.

Cecil,

You routinely confuse results and observations with underlying causes.

There is nothing wrong with s-parameter analysis. The problem is that you keep trying to make s-parameters something they are not. Did you perhaps notice that word "parameter"? Do you think there might be a reason that term was chosen rather than, say, "all encompassing equations describing the entire universe"?

S-parameters work fine for their intended purpose. However, they don't trump Maxwell's equations or solid state physics, nor do they try to.

Cecil,

You still don't believe in superposition, do you?

I don't need to worry about which of your purported answers is goofier
than the other. Superposition allows me to combine your traveling waves
into a standing wave. The energy analysis then becomes very easy, with
no paradoxes.

HP would simply observe that what b1 = 0 means is that there is no energy and there are no waves moving in the direction of b1.

I have suggested those configurations myself and those ideas
have been rejected by the other side - which claims that
all one needs to linearize a real-world source is a ten
cent resistor.

Nobody said they did, Gene, so this is just another one of
your straw men. EM waves canceling each other to zero are
perfectly compatible with Maxwell's equations. When you
use Maxwell's equations on two EM waves of equal amplitude
and opposite phase, do those equations really say that
the two waves, as you assert, never existed in the first
place?

You yourself have said that nothing is lost during superposition.
Presumably that includes energy not being destroyed.

Given that |s11(a1)|^2 = 1 joule/sec

Given that |s12(a2)|^2 = 1 joule/sec

Given that |b1|^2 = 0

What happened to the 2 joules/sec?

Yes, and HF also observes that, e.g.:

|s11(a1)|^2 = 1 joule/sec

|s12(a2)|^2 = 1 joule/sec

Presumably, HP doesn't believe in destruction of
energy. Hecht says those joules existed with a
direction and momentum toward the source. What
happened to those joules to reverse their direction
and momentum?

Clearly, according to everything that is known and is measurable,
those joules are not traveling in the direction you claim.

So you don't believe in any of the S-parameter analysis done on linear small-signal amplifiers, then. Might as well just toss HP AN95 in the trash. Might as well toss the S parameters provided by pretty much all the RF transistor manufacturers in the trash. And in fact, even beyond that, you don't believe in any of the S-paramter analysis done on any system that's propagating power, because that power came from a source, and if you toss one non-linear element into the system, the whole system is non-linear and none of this linear systems analysis would be valid.

Enjoy your dreams, whatever kind they may be. Fortunately, they won't keep the rest of us from continuing to successfully analyze our systems, including the sources, with H parameters, Y parameters, S parameters, or just plain old elemental linear circuit theory.

From the labs,
Bunsen

> I don't think they do.

Take a look at pages 16 & 17. Quoting:

"Another advantage of s-parameters springs from
the simple relationship between the variables
a1, a2, b1, and b2, and VARIOUS POWER WAVES."

Definitions of |a1|^2, |a2|^2, |b1|^2, & |b2|^2
follow.

"The previous four equations show that s-parameters
are simply related to power gain and mismatch loss,
quantities which are often of more interest than
the corresponding voltage functions."

Definitions of |s11|^2, |s22|^2, |s21|^2, & |s12|^2
follow.

On page 10 it says: "The s-parameters s11 and s22
are the same as optical reflection coefficients;
s12 and s21 are the same as optical transmission
coefficients."

In fact, the intensity equation from optics can
be had from squaring both sides of:

b1 = s11(a1) + s12(a2)

They certainly work for systems designed to be linear
as are *linear* small-signal amplifiers, sources with
circulators, and padded sources as I have said over
and over.

Amateur transmitters are not designed to be linear
and they are NOT linear. Adding a ten cent resistor
to them is not going to make them linear.

You really don't WANT to think outside of the box that
you have built for yourself, do you. Anyway, reread
what I wrote and work out why your response is a
non-sequitor.

> Calculate the number of electromagnetic joules in
> the line and get back to us on how they are reflected

You really are stuck in a box. Consider a capacitor.
It has no difficulty storing energy without velocity.
And lest you say, "but that is not a transmission
line", consider an open circuited transmission line
excited with a step function. After settling: constant
voltage, no current, energy stored in capacitance,
and the DC coupled directional wattmeter will
tell you there are the same number of 'Bird watts'
going east as there are 'Bird watts' going west

...Keith

But I still don't see where HP said that either s11(a1) or s12(a2) is equal to the square root of 1 joule/sec. Which pretty much confirms what I said. I think you might have made that part up to try to sound authoratative.

But I will concede that if you had been right, it may have lent support to your contention that waves and energy are moving in the direction of b1 while not moving in the direction of b1. :-)

Roy Lewallen, W7EL wrote:
"The attenuation of the ground wave is the same as the free space attenuation?"

No, it is greater. The attenuation of the ground wave is more rapid because the soil has resistance and imposes a loss on the passing wave.

In free space, there is no ground loss and the signal loss is from the spreading of the signal which reduces its density. It declines 6 dB (its power is quartered) every time the distance from the transmitter doubles, that is its volts per meter or signal strength is cut in half.

Ground waves decrease more rapidly with distance from the transmitter due to imperfect conductivity in the earth`s surface. Loss goes up with the operating frequency and with higher resistivity in the soil.

The FCC`s ground-wave field intensity charts cover limited frequency ranges and each curve is for a specific soil conductivity.

Best regards, Richard Harrison, KB5WZI

Keith Dysart wrote:
> You really are stuck in a box. Consider a capacitor.
> It has no difficulty storing energy without velocity.

Uhhhh Keith, a capacitor cannot store an EM wave which is photonic energy. If a capacitor stores the energy in an EM wave, it must first convert the EM wave energy to some other form of energy, e.g. electronic energy. That is certainly possible, but the energy ceases to be EM energy and cannot be recovered as the same EM energy coherent with that which was stored. If thinking outside the box requires a complete denial of reality and the laws of physics, then I think I will pass.

To summarize, converting EM energy to electronic energy causes the EM energy to lose coherence. It would take heroic measures to recover that coherency and those measures simply do not exist inside a transmission line.

It certainly seems that you guys don't understand the difference between photonic energy and electronic energy and you treat them as if they were interchangeable with no conversion process required. Hint: When energy is converted from one form to another, the previous form disappears and is generally not recoverable in a form coherent with the original. Yet, all the energy inside a transmission line remains coherent. You have generated a logical and technical contradiction.

> equal to the square root of 1 joule/sec.

Good grief, Jim, are you too lazy to perform the math???

Squaring both sides of the above equation to obtain
joules/sec:

b1^2 = |s11(a1)|^2 + 2*s11(a1)*s12(a2) + |s12(a2)|^2

Does that center term look familiar yet? It should since
it is the interference term in the intensity (power density)
equations from "Optics" by Hecht and from "Principles of
Optics", by Born and Wolf.

Let |s11(a2)|^2 = P1 Then s11(a1) = SQRT(P1)

Let |s12(a2)|^2 = P2 Then s12(a2) = SQRT(P2)

Is your mental light bulb coming on yet? Assuming the phase
angle between a1 and a2 is zero, we can directly write the
equation for total constructive interference.

Ptot = P1 + P2 + 2*SQRT(P1*P2)

Could you clarify; At what frequency does the signal in the transmission line become "EM" energy? A step function has high frequency components, and yet the end result is DC. Did it stop being "EM" energy at some point? Which point?

Or how about a square wave at 0.00001 Hertz? "EM" energy? Or not? Harmonics are only limited by the rise time. But my meter will have trouble knowing its not DC.

That shows exactly how much you understand the s-parameter analysis. The s-parameter voltages have been normalized such that the square of the normalized voltage is indeed equal to joules/sec. If you had paid attention, or were half as smart as you think you are, or even read HP Ap Note 95-1, you would have realized that fact a long time ago and not be showing your ignorance here and now.

> From which it follows that 0 = 4.

Obviously either an ignorant response or an obfuscation.
It follows that the result of destructive interference is zero while the result of constructive interference is 4, just as Born and Wolf asserted in "Principles of Optics", Chapter VII.

Imin = I1 + I2 +2*SQRT(I1*I2) = 0 equation (16b)

Imax = I1 + I2 + 2*SQRT(I1*I2) equation (16a)

If I1=I2, then Imax = 4*I1 equation (17)

There's your 0 and 4, Jim, straight from Born and Wolf.
Now you can assert that Born and Wolf have been discredited just as you asserted that Hecht has been discredited.

What dimensions do you get when you perform the
following operation using the s-parameter dimensions
of a1, a2, b1, and b2?

[volts/SQRT(Z0)]^2 = _____________

Apparently, that is a really tough one for you since
you have failed to comprehend it for weeks now.

[volts/SQRT(Z0)]^2 = volts^2/Z0

Maybe if I simplified it to V^2/R, you would recognize
it as joules/sec?

no.. Clarke orbit (e.g. for Dish Network or DirecTV)

There are some orbiting TV satellites in Molniya orbits for covering Siberia that might be useful. They radiate in C band, and perhaps Ku?

The GOES polar orbiters radiate at 1.6 GHz, and I'm sure there's others out there. GPS radiates at several L-band frequencies.

ISS radiates in S and Ku bands and is in LEO, as is the Shuttle when it's up. I don't know if they would be useful as a source though, because the antenna is directional and probably pointed at TDRSS or a ground station.

From: Wayne <mygarbagecan@verizon.net>
Message-ID: <jOdXh.2816$nR1.1295@trnddc06>
Source record: 42356

Let's say that I have a set of S parameter data in the form rho+angle. The parameters are S11(ant) for an antenna, S11(cable) and S21(cable) are for the cable. S12(cable) and S21(cable) are assumed equal.

S11(system) is for the antenna and cable connected together. How would the S11(system) be calculated?

As a first stab at it, I would calculate:
S11(system)=S11(ant) * S21(cable) * S12(cable)

Is that valid, and/or does S11(cable) need to be included?

Thanks

I'm contemplating a Yaesu TF-857D with the FC-40 antenna tuner as a base rig. I'd like to cover as many HF bands as possible with a simple wire antenna. I'm on a small lot with an 80' tower. So anything I put up is going to slope!

I've never used an antenna tuner before. I believe the FC-40 is weather proof and meant for remote use.

If I slope a random wire and end-feed it, should the tuner go up on the tower or stay on the ground? (In other words, which end should I feed?) How should I ground the FC-40?

Anything better than a random wire that is still simple and covers all/most of the HF bands?

I'm not really that bothered about the depth of nulls to any great
extent. Since this is radiating an unwanted signal, the concern is
finding where the gain is highest and how high it is.

Hmmmm

This one seems to be another multifolded resonnator non-radiator concept
from the $hitizen bandits. If you need such bullshit, there's no need to
pay buck$ for it if you can homebrew it so easily.

If you cannot afford homebrewing, then go for a real antenna! Cushcraft used
to make good multiband verticals such as the AP8A or the R7/7000-R8 series.

If you already have a "tuner" you can homebrew a 1/9 Un-Un ï¿œ la ZX-Yagi MTFT (Miracle Tranformator For Totaly-dumb-people) and hook it to your 80' pole... Guarated under 20$ including plastic box, silvered copper wire, inox screwery and BNC socket. For low band action you can slide a ferrite bar in it.

Hello,

By the way, there is also the OCFD (Off Cetered Fed Dipole) covering from 80 up to 10 + eventually WARCs or the Levy, but with the Levy you'll need a specific Levy tuner... But it can be easily homebrewed.

And the antenna is one of the last part of the radio equipment we can afford experimenting with, without spending much money (nor time).

Take a look at the 88 Ft center fed Dipole. 80--10 Meters with pretty
good results. You can find out more at
http://www.cebik.com/edz/88.html
Of course you'll need a good Antenna Tuner also.

Good luck

I have been tinkering with an SGC-237 Tuner and I have concluded:
A tuner will match most anything.
A tuner does not change the antenna system, it only matches it.
An antenna still works best at its resonant frequency. (best is in
the eye of the beholder!)
If you use a vertical radiator against ground, the ground system is
still as important as the radiator.
Evaluating the configuration is mainly guesswork.
You can save yourself a lot of time and effort by modeling a given
configuration with EZNEC.
Your antenna begins at the connection to the tuner.

The antenna I discred has a gain of about 20 Dbd and the far field doesnt
form up at 2Km like I said. Monitoring devices shuold be at least 2km awy to
make sure they are in the far field so my guess would be about 1/2 that
distance.

What if he goes near the top, places the tuner there, one side to the
tower, the other side to an 80 foot wire sloped out as far as he can
go to the edge of his property, and as high as possible.?

"Works best" needs a definition. An Extended Double Zepp
is not resonant but "works better" than a resonant dipole
by about 3 dB broadside.

A simple end fed wire is complicated by the fact that it will need a
good ground system.

A sloping dipole, or an inverted V dipole coming off your 80 foot
tower, will need no ground system, though. So the dipole might be
easier.

Source record: 42372

oops...I have changed the wording in a couple of places, and restated problem below:

Let's say that I have a set of S parameter data in polar form. The parameters are S11(ant) for an antenna, S11(line) and S21(line) are for the transmission line. S12(line) and S21(line) are assumed equal.

S11(system) is for the antenna and cable connected together. How would the S11(system) be calculated?

As a first stab at it, I would calculate:
S11(system)=S11(ant) * S21(line) * S12(line)

Is that valid, and/or does S11(line) need to be included?

Thanks

Hi Cecil -

I included your entire post - Keith's remarks and yours. Please
refrain from making ad hominem remarks. Particularly baseless ones.

> > Ever hear of a CCD camera?

> I've never heard of a CCD camera that stored EM waves.

The context of your remark, which you have now deleted, was "energy
from EM waves". The little capacitors in a charge coupled device store
the light energy until it is read-out and converted to digital.

The context was "EM wave energy that remains unchanged
without being converted to some other form of energy".
If that context was not clear to you, I apologize.

When I say "EM wave energy", I am not talking about extracting
energy from EM waves. I am talking about energy continuing
to exist in the form of EM waves while obeying all the
boundary conditions for EM waves.

The energy in RF standing waves is recovered during the
power-down transient period as EM wave energy, not as
a DC charge on a capacitor. That means that the energy
in the standing waves is not standing still since EM
energy must necessarily move at the speed of light, c(VF).

Cecil--
The s-parameter threads caused me to resurrect some test data that was taken (by an RF engineer) before I retired. I never looked at the data other than to see if the antenna system components met specification.

So, I have s parameters for each component taken with the latest/greatest HP/Agilent VNA at the time. For coax cables, the VNA was connected to each end of the coaxial cable for the measurements. Antenna data was taken with one port of the VNA connected to the antenna input, which was a SMA connector. The antenna was a s-band cavity antenna with a 1/4 wave probe. The components were all 50 ohm nominal. Hopefully, this answers your questions.

I'm curious about how to use the s-parameters for components to calculate the "system" s-parameters. The original question is about a single antenna fed by a transmission line, but I will probably try to analyze more complicated hookups later.

Thanks
Wayne

Nice CYA, Jim, but the context was the normalized
voltages used in the s-parameter analysis. I posted
the s-parameter equation, b1 = s11(a1) + s12(a2) = 0,
and said that squaring it yields joules/sec. Your
statement was in direct response to that statement
of mine.

If you knew that squaring an s-parameter normalized
voltage yields joules/sec and still made that misleading
statement, you were deliberately engaging in false
implications. Why are you more interested in
obfuscation than in the truth?

If I correctly understand what you say, you have the trivial
one-port case of the antenna and the two-port case for the
transmission line. HP's Ap Note 95-1 might be the place to
start in understanding a basic analysis.

Yes, the measurements are one-port for the antenna and 2 ports for the line.
My question was asked after looking at the referenced website, and trying to
apply the information.

So, to avoid having to return to previous messages:
Can the S11 of a line connected to an antenna be calculated as:
S11(system)=S11(antenna) * S21(line) * S12(line) ?

Thanks
Wayne

Hmmm. energy in a light wave is separate and distinct from energy from
EM waves. Must be the subtle distinction between "in" and "from"
waves.

Well, now that Vaudeville is dead, the entertainment value has gone to
hell.

Check out http://www.rfcafe.com/references/electrical/s-h-y-z.htm
The usual method would be to convert the S matrices to ABCD
matrices then perform matrix multiplication on the cascaded
ABCD parameters. You then convert the resultant ABCD matrix to
an S matrix.
http://www.mathworks.com/access/helpdesk/help/toolbox/rf/index.html?/access/helpdesk/help/toolbox/rf/rfckt.cascade.html&http://www.google.com/search?hl=en&q=cascaded++s+parameters&btnG=Google+Search

Cecil,

The generally accepted description for energy density in an
electromagnetic field is:

W = 1/2 (E dot D + B dot H)

All the variables on the right side are vectors. The total energy can be
determined by integrating over the volume of interest, of course. This
relationship holds for either static or time-dependent fields. You can
find this equation in virtually any E&M textbook, but I can provide
specific references if needed.

Do you have a definition for "EM wave energy" that differs from the
standard equation? Are there multiple forms of electromagnetic energy?
Is is necessary to convert "to some other form of energy" when the
entire problem is about electromagnetic fields?

Inquiring minds want to know.

Thank you Richard for such a kind word as "inadvertent".

I make mistakes and I apologize for them. Hopefully, none of consequence go uncorrected and mislead anyone. I learn more from my mistakes than from correct postings but it isn`t my favorite way to learn. Thank you to everyone who prompts me to search for the answer to an interesting question.

I`m still puzzled about "cluster antennas".

Best regards, Richard Harrison, KB5WZI

Yes. The statement was intended to point out to you that squaring an
equation expressed in units of volts does not convert the expression
to power in units of Joules per second.

So, was it also a typo when you squared s11(a1) + s12(a2) = 0 and
claimed that s11(a1)^2 = s12(a2)^2 = 1 Joule/sec? :-)

Not at all. s11 and s12 are dimensionless. The units of
a1 and a2 are volts/SQRT(Z0). What do you get when you
square volts/SQRT(Z0)?

Hint: [volts/SQRT(Z0)]^2 = V^2/Z0 = joules/sec.

Most likely due to lack of a defintion of "Gaussian Field". The only
accepted defintion has to do with statistical analysis and not antennas.
If I remember correctly Gaussian Field had to do with Gauss's study of the
distribution of matter in the universe. If this is not what you are talking
about I suggest you find another name for it as it is difficult to think of
your meaning of it while excluding the normall accepted meaning. Perhaps it
should be called the Unwin field, Im sure Gauss wouldnt mind. and credit
should be given for such work where credit is due. Kraus, the author of,
Antennas, had a very fine style of writing where he included mathematic
formulae along with a verbal disrciption, each adding support to the other.
This form would probably be more than acceptable for any form of peer
review.

Jimmie

>
> 0 = 4

Sorry Jim, you got it wrong (again). s11(a1) and
s12(a2) are 180 degrees out of phase so the |b1|^2
equation is actually:

|b1|^2 = [s11(a1) - s12(a2)]^2

Expanding:

0^2 = [s11(a1)]^2 - 2*s11(a1)*s12*(a2) + [s12(a2)]^2

0 = 1 - 2 + 1 = 0 (but you knew that already)

That's total destructive interference in action just
as Hecht and Born & Wolf explain. Your equation
above is actually for |b2|^2 in the direction of
the load where the constructive interference is
taking place.

Please stop your unethical practice of trying to imply
that something is wrong when you know it is not wrong.

For b1 = 0, s11(a1) and s12(a2) *must* be 180 degrees
out of phase.

cos(180) IS NOT AN ARBITRARY CHANGE!

cos(180) = -1 (but you knew that already)

Cecil,

Once again you completely avoided the straightforward question. I gave you a universal equation for electromagnetic energy. You come back with all sorts of waffling about "photonic TEM energy waves", but with zero substance.

Forget about standing still or moving; do you have any reference that mentions "photonic TEM energy waves"? If so, what behavior is attributed to such beasts? What is the equation that describes the energy in "photonic TEM energy waves". Is there a conversion factor to convert into plain ol' ordinary electromagnetic energy?

Do you simply make this stuff up as you go along, or do you have notes from years of fantasy?

The equations were phasor equations, Jim - no negative
sign necessary at all. (But you already knew that)

Please stop the obfuscations. You know full well that
cos(180) can be replaced by -1 and that subtraction signs
are never necessary for phasor subtraction. There is no
problem using a plus sign in the following equation.

b1 = s11(a1) + s12(a2) = 0

It just means that s11(a1) and s12(a2) are 180 degrees
out of phase with each other. (But you already knew that)

Joules per second doesn't have phase, Cecil. Your claim was the value was 1 joule/sec. And the equation is stated pretty clearly in AN-95-1 as the sum of the terms. It doesn't have a minus sign, and it there isn't a cosine term in it. a1 and a2 are complex voltages, and their relative phase take care of itself - unless of course you square the equation. That's how you end up with nonsense like 0=4.

I'm done with this.

No, I answered in a straightforward manner. You just didn't
like the answer.

RF energy in a transmission line is photonic. Photons
always move at the speed of light. Therefore, photonic
energy cannot stand still. QED in more ways than one.

As you know, I have repeated all this to you before so
you cannot possibly still be confused. Why you continue
your obfuscation of the truth is really strange.

b1 = s11(a1@0deg) + s12(a2@180deg) = 0

1. When we square both sides of the equation, the
product of 2*s11(a1@0deg)*s12(a2@180deg) is at 180
degrees so the sign of the term is negative. (but you
already knew that)

2. Joules per second doesn't have phase. I have said that
over and over. The phase term in the power density
equation is the relative phase between the two associated
voltages. (but you already knew that)

3. The equation stated in AN-95-1 is a normalized voltage
equation which is the sum of phasors - no negative sign
required for phasor addition. (but you already knew that)

4. Phasor symbols don't have minus signs and the real value
of a phasor is understood to include a cosine term even
though it is omitted by convention. (but you already knew that)

5. The general case of the squared equation is the same
as the intensity (power density) equations from Hecht
and Born & Wolf. It doesn't contain a minus sign.

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(A)

A is the angle between the two associated normalized
phasor voltages, a1 and a2, and its cosine is sometimes
negative. (but you already knew that)

I did not end up with nonsense like 0=4. You ended up
with nonsense like 0=4 by engaging in deliberate
irrational obfuscation. Why you feel the need to
act that way is really strange.

Cecil,

The question was about your claim that there are different forms of electromagnetic energy. Now you are trying to switch the topic to some babble about photons and the speed of light.

I guess you cannot answer the energy question. This is not surprising, since there is no valid answer that brings in some additional form of electromagnetic energy.

Actually, looking at it again, for b1 to be 0, the
following would have to be mathematically true.

b1 = |s11(a1)| - |s12(a2)| = 0

Now square both sides of the equation and see what
you get.

The electromagnetic force is one of the four fundamental
forces of nature. It can certainly exist in forms not
associated with photons. Excess electrons stored in a
capacitor is an example of electromagnetic energy devoid
of photons.

It is generally accepted that RF TEM waves are photonic in
nature being the result of accelerating and decelerating
electrons in a transmission line. If you agree with that
notion, then you must also admit that RF TEM wave energy
cannot stand still and the appearance of such in a
standing wave is just an illusion. Otherwise, you need
to disprove the notion that RF TEM waves are photonic.

5101. How to set Sony car stereo from Japanese to US tuning...service manual help anyone?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-25 06:07:58 UTC
From: gggoattt@aol.com
Message-ID: <1177481278.048817.61860@b40g2000prd.googlegroups.com>
Source record: 42217

I need to set the tuning on my Sony car stereo from Japanese to US tuning; service manual?

Hi there...

I was wondering if someone has any idea if ANY of the Sony "WX" series of double-din car stereos (japanese or usa models) can be "hacked" so that their tuners can be changed from japanese fm tuning to us/uk or world band tuning and vice-versa???

I recently purchased a Sony WX-C88REC double-din cd/md recorder from eBay. This is a japanese market deck and is factory set for japanese fm tuning. However, the design and physical layout of this deck is very similar to other US models (such as the WX-4500X and the WX-C5000, as well as the WX-C55 which looks nearly identical). I'm nearly convinced that there MUST be some way to hack the japanese models so that their tuners can be "switched" to us or world tuning. I find it difficult to believe that Sony would design two distinct different tuner hardware modules for japanese and american versions. Problem is, I have no clue HOW to "hack" this feature. I don't have a service manual for ANY "WX" series stereos, but I'm thinking that it may possibly be an option in a service manual for ANY of the "WX" decks. Again, I find it difficult to believe that this isn't "set-able" some sort of way.

Does anyone out there have an idea? Does anyone out there have ANY service manual for ANY "WX" series Sony stereo? Or, for that matter, does anyone have a service manual for ANY Sony car stereo that addresses in ANY way setting the tuner for different bands?

I realize there are adapters available to transpose the FM frequencies. I've used them before, always with poor results (stations usually overlap and are weak). I mainly record off the radio with my MDX-C800REC's in my other cars, but always thought it would be cool to be able to dub cd's quickly in-dash digitally without having to mess with a cd changer. But, radio recording is my primary concern...and the adapters don't provide the quality I want for recording.

PLEASE help ANYBODY if you can steer me in the right direction or help in ANY way. If anyone has ANY Sony service manuals for ANY stereo, please let me know...perhaps if setting the tuner IS an option, maybe it is a standard procedure to set ANY Sony stereo's tuning in a similar fashion.

Thank you VERY much!
Jeff

The context of the present discussion is a Z0-match point
at which reflections toward the source are eliminated.
For the case of a Z0-match, the cosine of the phase term
will indeed always be +1 or -1 as the fields are either
in phase or 180 degrees out of phase.

If the SWR is 1:1, there is no reflected voltage and
therefore a2 = 0 and there is no assignable phase angle
between the voltages.

In the general case, where reflections are allowed to
reach the source, the cosine value can be anything
between +1 and -1 as the angle between a1 and a2 can
have any value between zero degrees and 360 degrees.

Apparently, you cannot afford to disagree with my posting.
Now consider the boundary conditions for a photonic wave
and you will probably agree with me that the energy in
a photonic wave cannot be stored in a capacitor without
an energy transformation from photonic energy to something
else. In short, photonic waves that appear to be standing
still are an illusion. Photonic waves cannot stand still.

Cecil,

I keep asking, and you keep evading. What is that "something else"?

You said that the energy must be transformed. I gave you the energy equation that describes the general electromagnetic case, whether stationary or "photonic waves". I have not seen any argument to that equation or any supplement to that equation.

You continue to waffle, but you still have not given the slightest hint regarding the required energy transformation.

For the record, I do not agree with your statement. No energy transformation is necessary. The working rules for this stuff have been known forever. There is no need to invent new junk science other than to prop up all of your other junk science.

All energy, by what is euphemistically called the "conservation of
energy," balances between a combination of Potential Energy, and
Kinetic Energy. There are no others, and they are simply the same
thing in different inertial references. Energy is inclusive of both.
What Cecil is laboring under is the wholly misapplied elevation of
plebeian units to the Olympian stature of fundamental forces.

I've already given you an example, Gene. Here is another.
I have a solar cell that transforms the energy in photonic
sunlight to DC energy stored in my deep-cycle marine battery.
Do you really think you could get a suntan from my deep-cycle
marine battery without another transformation back to UV?

> I have not seen any argument to that
> equation or any supplement to that equation.

I only respond to the part of your posting with which
I disagree. Here's an equation for you: 2 + 2 = 4

Since that same equation works on cows and dollars,
do you really expect us to believe that there is no
difference between cows and dollars? Please get real.

> For the record, I do not agree with your statement. No energy
> transformation is necessary.

OK Gene, then explain exactly how photons can be stored
in my deep-cycle marine battery without a transformation
from photonic energy to electronic energy. Why haven't
you patented that RF battery idea of yours?

I've cut and machined a fair amount of Extren (pultruded structural
fiberglass composites) and things like glass-epoxy laminate over the years.

-> cutting glass fibers makes tools dull in a big hurry, even carbide,
the wear rate is spectacular.
-> diamond tooling survives quite well and isn't all that expensive
-> or, just buy cheap tools and throw them away after a couple uses
(e.g. drill bits)
-> the dust is quite obnoxious and abrasive, avoid getting it in the
ways or anything that needs high precision. lots of liquid coolant
helps keep the dust to a minimum
-> breathing the dust is bad, getting it on your skin is bad, getting it
on your clothes is bad. Consider wearing one of those disposable tyvek
coverall suits. Try and keep the dust from spreading, because
inevitably, you'll pick it up later, and it itches, if nothing else.

-> these are the reasons why machine tools used to machine glass or
carbon reinforced composites sell at a discount.. they wear out fast..
all those little abrasive particles grind away at all the precision parts.

Unless you're going to be doing a lot of it, you might be better off
just paying a machine shop that handles the stuff to do it for you.
Places that regularly machine laminates and composites have all the dust
collection stuff and tooling, and factor the wear into the price structure.

When I started working with composites at a former employer, they had
only done machining on conventional metals and plastics. After my
little foray into composites, they decided it wasn't worth it. Metal
scrap is easy to manage, little bits of glass fiber isn't.

Over the years I've often been totally puzzled by things people do which don't seem to make the least bit of sense. But I've come to realize that the actions often make perfect sense -- it's just that I had a mistaken idea of their motives. For example, an action which might be totally baffling if one assumes that the motive is the best interest of the country suddenly makes sense when one realizes the the actual motive is to enrich one's friends or to increase one's power. So here's some help in understanding the process we've observed here:

In certain regions of the country, "winning" is paramount to one's self-image -- indeed, to one's very manhood. And the sole criterion for winning is to be the last man standing. It appears that we are, once again, nearing the point of declaring a "winner", and it will be the same person who has "won" countless other threads by the same means. Sometimes it's easy and sometimes hard, but he's the undisputed master and will not be defeated. Everyone who has thought that logic and reason, rather than plain chutzpah and tenacity, are paramount, will be humbled when the clear winner -- the last man standing -- is declared.

Congratulations, Cecil! Your reputation among your peers is intact.

Roy Lewallen, W7EL

Technical truth is the only winner here, Roy. Nobody
has provided an example of a standing wave existing
without the component forward and reverse waves.
Nobody has explained how the photons in the standing
wave can possibly stand still. Looks like the wave
reflection model is alive and well in spite of the
obvious agenda to kill it off.

Are you still standing by your use of standing wave
current with its unchanging phase to "prove" that
there is no phase shift through a loading coil? I
can also use that same technique to prove there is
no phase shift in a 90 degree stub.

Sir, I've built more antennas since 1964 than you can count. Including scewdrivers (www.qsl.net/k4kwh) In this case, the one I recommended (since he didn't say specifically) was because I had some illness/death at home, I wanted to cover 160 Meters in a small lot, and I couldn't devote the time to building an antenna at the time. I beg to differ with the non-radiator antenna comment. KNOW of which you speak.....like actually reading the reviews of it on www.eham.net.
There ARE reasons for the choices we make! The Cobra WORKS, and next time, yeah, I will probably make one as I now have the time I did not have prior to my Father's illness and death!!! :(

This is all because 'standing waves' don't exist! they are a figment of early experimenter's attempts to make tuning measurements on open wire lines using improvised tools. Because the current or voltage peaks and dips they were measuring seemed to be wave shaped and occured at intervals of 1/2 wavelength along their feedlines, and didn't move, they called them 'standing waves'. A complete misnomer, but quite adequate for the purpose they were used for... and are still used for. Though today we understand that the effect is caused by the superposition of forward and reflected waves and can measure the separate component waves, the legacy term still remains in common use.

Ah, the Cobra! An interesting antenna for exploration of the myth that
linear loading is essentially lossless, see my analysis of NEC models of a
Cobra design at http://www.vk1od.net/cobra/index.htm .

No, yet another person who believes that forward
waves and reflected waves do NOT interact and
therefore maintain their separate identities
moving at the speed of light in opposite directions,
in accordance with the wave reflection model.

no, i heartily DO believe in superposition. what i hate the misnomer
'standing waves' that has misled many non technical people to an incorrect
view of how waves work.

Hi Roy,

It seems this technique has become rather commonplace as a recent
complaint of mine would reveal, and few are interested in snorkeling
through the sewer to find a lost reputation.

Recommendations for searching the archives should be confined to
finding facts, which are few and more easily described in the
constraints of a search engine; looking for evidence of distortions
would cripple the bandwidth capacity of the Internet.

>
> Best regards, Richard Harrison, KB5WZI

I really don't know why it puzzles you. I have determined that coupling of elements which means parasitic coupling is wastfull. To avoid this coupling one must have elements that are all resonant. This means ofcourse that element dimensions are necessarily different from neighboring elements so that coupling per se (there is no attraction or repeling actions between elements) removed which thus creates an arrangement that is in equilibrium. When elements are associated with each other one can call them a 'collection' of elements or a 'cluster' of elements. Now with respect to efficiency this array does not have coupling associated with reflectors and directors thus if the array was energised then a far field of radiation is formed without any wastefull interaction of particles between elements. So when the far field is formed the only "waste" of energy is that created by skin resistance which is easily calculated, since without interaction between elements non radiating energy collision losses cannot occur. If one is looking for efficiency one usually work with input energy equals output energy plus losses. When one is examining the amount of radiation formed in the far field because one does not want to get into a situation of interactive bombardment of partcles that do not contribut to radiation in the far field prior to the generation of radiation. This analysis I suppose can be considered a simple relationship with Poyntings vector and in a way provides support for Poynting where none existed before but I may be over reaching there in some eyes. Hope that satisfies your curiousity

Hi Danny,

You will see that the FR card has a symbolic variable for the frequency, you will need to feed it a float value. (I used a PERL script to run a series of models by tailoring the basic NEC deck, executing it, and summarising the results.)

Differently to many of the commercial Cobras, my model used 2mm dia copper and wider spacing. Most seem to use smaller, even very small spacings where proximity effect becomes significant, smaller conductors, and possibly steel cored copper clad conductors.

IMHO, the interesting aspect of the article is the loss mechanism of linear loading, it makes sense once you see the current magnitudes and phase and realise this thing at some frequencies carries large conductor currents for low net current moment.

I have been exploring a 13m unloaded vertical with 2 radials for each of 80, 40, 30, & 20 metre bands, and there is a different but similar (!!!) effect where at some frequencies the radials carry large individual currents (larger in magnitude than the current in the vertical) with a peak in loss at these frequencies, see http://www.vk1od.net/multibandunloadedvertical/13mEV-1.gif .

No problem Owen, I'll use MultiNec which very easily allows me to run
"test cases" using variables with no programming required on my part.

Ok. There are other tools that allow symbolic variables, and of course NEC allows specification of a range of frequencies on the FR card.

The main reason for using PERL to build, run and sumamrise is the summarise stage. At that point I merge the NEC output with real transmission line models, L-tuner models etc... and without wading through 5MB of NEC output by hand. The system view is a bigger picture than the NEC output.

The standing wave current phasor has the "same rotational speed
as its components"??? How can that be when the forward current
phasor and the reflected current phasor are rotating in opposite
directions?

Your statement above is in direct contradiction to Kraus's
graph of phase on a 1/2WL dipole where the current phase from
end to end varies away from 0 degrees by only a couple of degrees.
EZNEC agrees with Kraus. That graph is Figure 14-2 on page 464
of "Antennas for all Applications", 3rd edition. EZNEC says
the phase of the current on a 12WL dipole varies by only
two degrees over the entire antenna.

If the phase of the net current doesn't vary end to end on a
1/2WL dipole, how could you and W8JI use it to try to prove
that the phase shift through a loading coil is zero degrees?
Isn't that called assuming the proof?

You didn't mention if it's a metal lathe or a wood lathe. If it's a metal lathe, it should be no problem getting a good uniform diameter. For one-off or just a few you can use either a HSS or carbide tool. Protect the lathe parts, especially the bed, from the abrasive dust. If you're worried about breathing the dust, keep the piece wet while you're turning it. You probably don't need to, but you can sand the tool marks out if you really want.

Your last sentence makes me think it may be a wood lathe. You should be able to do ok with that too. Be careful about the tool digging in and grabbing, of course. If you really don't want to try a standard wood lathe tool on it, you could perhaps make one from an old (or cheap) file; it would be a lot harder than a random piece of square steel stock. Another possibility is a HSS metal lathe bit, mounted in some suitable holder.

I certainly wouldn't think twice about turning fiberglass in a metal lathe, with proper protection.

Cheers,
Tom

I have a small lot with an 80 ft tower. It's about 90 ft from the tower to the farthest edge of my property. I figure any multi-band HF wire antenna I put up will have to slope. I have a couple questions:

1) If I go end-fed Random Wire with an external antenna tuner, what kind of ground does the tuner end require?

2) I see there are many Folded Dipole designs. Some with ladder line, some with coax, some that claim not to need antenna tuners. How well does a dipole hold up mechanically without being supported in the middle? (with the feed line just hanging down)

It's a little more subtle than that. I mean that the
output of an active dynamic class-C amplifier does not
lend itself to passive superposition. The component of
the sums is not the sum of the components.

> Or do you mean that the output aspects of a class-C amplifier

If a class-C amplifier is modeled as a linear circuit,
the model is wrong.

> The former is certainly true, but for the latter, it seems to me

But the model bears little resemblance to the actual
active dynamic source which has been my objection all
along. When the tube is off, the source impedance is
essentially infinite. It is like the energy tick provided
by the weights in a pendulum clock. One can assume that
the linear pendulum is the energy source but the weights
are actually the energy source and that energy is
delivered as a step function pulse.

Dave,

You say the words, but you gotta walk the talk.

When superposition applies, the superposed function is completely equivalent to the sum of the components. There are no remaining hidden variables still lurking in the original components, invisible to the standing wave.

When two traveling waves combine to form a standing wave, the standing wave result contains *all* the information and properties there are to be had. The standing wave is just as valid as the two component waves taken together.

Now Cecil (and others) may immediately come along and assert that we can take one traveling wave at a time and yadda, yadda, yadda. Sure we can, but it is now a different setup. He may also yammer on about all sorts of special cases, with transients, circulators, non-linear setups, and so on. Superposition does not always apply, but when it does, it works.

I have said many times that all of this is strictly a matter of mathematical convenience. In that regard there is some agreement with your assertion that standing waves were first recognized as a matter of expediency. However, standing waves are *not* an approximation. A correct standing wave function works just fine as a solution to the standard wave equation. No traveling waves are needed at all, but you can use the completely equivalent set of traveling waves if you prefer.

Let me remind you of what you said earlier - that all phase
information disappears from the phase of the standing wave
and that the phase information from the component waves is
contained in the amplitude of the standing wave. Conversely,
the amplitude information from the component waves is contained
in the phase of the standing wave. This is why standing wave
current cannot be used to measure phase shift and why standing
wave amplitude cannot be used to measure the "current drop"
through a loading coil.

Roy's and Tom's measured "current drop" is actually phase
delay information. Their phase measurement is actually
information about the amplitudes of the forward and
reflected waves. They apparently didn't (and still don't)
understand that fact.

> Now Cecil (and others) may immediately come along and assert that we can
> take one traveling wave at a time and yadda, yadda, yadda. Sure we can,
> but it is now a different setup.

This seems to contradict what you said in the paragraph just above.
Taking the component waves together is either valid or it is not,
no if's and's, or but's.

> I have said many times that all of this is strictly a matter of
> mathematical convenience. In that regard there is some agreement with
> your assertion that standing waves were first recognized as a matter of

The problem is that some people have been seduced by the standing
wave solution not realizing that the constant standing wave phase
cannot be used to measure phase shift. Roy's and Tom's measurements
of standing wave phase through a loading coil are meaningless yet,

to the best of my knowledge, you have not voiced an opinion about those bogus measurements.

> No traveling waves are needed at all, ...

The question is not whether, when properly implemented, a standing wave analysis yields valid results. The questions are:

1. Can the component forward and reverse traveling waves be used to obtain a valid solution? If the answer is no, then the superposition principle is invalid. If the answer is , yes, then why do you object?

2. Have some people made errors in their analysis using standing waves? The answer is obviously, yes, since standing wave phase was used for loading coil phase delay invalid "measurements".

Incidentally, everyone (including me) was wrong in the
discussions back in 2003. There were two sides to the
argument and both sides were partially right and partially
wrong. The correct answer lies somewhere in between the
two positions.

The key to understanding the phase shift through a
loading coil is in first understanding how a stub
that is physically 41 degrees long can cause 90
degrees of phase shift. Here's an example:

---30 deg 450 ohm line---+---11 deg 50 ohm line---open

The above stub is physically 41 degrees long and
electrically 90 degrees long. Understanding how that
is possible is the key to understanding how 30 degrees
of coil and 11 degrees of stinger can resonate as if
it were 90 degrees long.

There is NOT (90 - 11 = 79) degrees of phase shift through
the coil.

There is NOT zero degrees of phase shift through the coil.

There *IS* 30 degrees of phase shift through the coil.

Art wrote:
"I have determined that coupling of elements which means parasitic elements is wasteful."

A parasitic element is normally constructed of low-loss material and re-radiates all the energy it absorbs from the radio wave. If it is placed and phased right it can reinforce radiation in the desired direction.

Kraus in the 3rd edition of "Antennas" has his close-spaced all-driven W8JK array and a wide-spaced all-driven 2-dipole array in the same figure, Fig. 6-12, on page 184. The gain of either antenna is about 6 dB, supposedly with respect to an isotropic, or about 4 dB with respect to a dipole. Both arrays are bidirectional.

Arnold Bailey catalogs a version of the W8JK close-spaced all-driven array on page 511 of "TV and Other Receiving Antennas". On page 516 is a 1/2-wave radiator with a 1/2-wave parasitic reflector 1/4-wave behind it (a simple Yagi).

Bailey gives the W8JK a resistance of 7 ohms and a gain of 4 dBd (6 dBi).

Bailey gives the parasitic array a resistance of 28 ohms and a gain of 5 dBd 7dBi). The parasitic array is slightly unidirectional while the pattern of the W8JK is symmetrical.

Best regards, Richard Harrison, KB5WZI

5151. Reciprocity of vertical antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-26 18:06:59 UTC
From: David <nospam@nospam>
Message-ID: <oq-dnXlJNLmnd63bnZ2dnUVZ8tyqnZ2d@bt.com>
Source record: 42167

The text below applies to vertical quarterwave antenna in free space with four quarterwave radials.

In transmit mode, the field from the radials cancel out.

When the antenna is receiving, the incoming wave interacts with the radials and is reflected into the vertical element.

How does this fit in with the antenna reciprocity theorem? The antenna field arrangement is working in different ways between transmit and receive. In transmit mode, the radials cancel out, and in receive mode the radials reflect the wave to develop a signal in the vertical element.

In receive mode, the radials strengthen the signal in the vertical element by reflecting RF energy into the vertical element and also providing the other half of the antenna by providing a RF ground side. The signal exists as a potential difference between two conductors.

In transmit mode, the radials have a standing wave on them and provide the RF ground side by 'converting' the high voltage at open circuit end to a low voltage (RF ground with high current) at base of antenna.

Do the radials have a standing wave on them in receive mode? Does antenna reciprocity theorem agree that the antenna can form same feedpoint impedance and field pattern in both transmit mode and receive mode, even though the electromagnetic field works differently? Are the electromagnetic field patterns noticeably different according to whether antenna is receiving or transmitting?

The vertical element is always known as the radiating element.

Wide bandwidth combined with small size is usually a bad sign. Physics
tends to make small antennas narrow banded, unless they are lossy.

In the product development world, we say "Fast - cheap - good: pick any two." Antennas are subject to a similar constraint, as Jon points out - "Small - broadband - efficient: pick any two."

No. The wave strikes the radials. This induces currents in the radials. Those currents cause radiation, and also the currents are conducted to the feedpoint. When the signal is coming from directions in which the radial radiation was zero, the induced currents will add to zero at the feedpoint, and the re-radiation will be zero in those directions.

> How does this fit in with the antenna reciprocity theorem? The antenna field
> arrangement is working in different ways between transmit and receive. . .

No, your concept of how it works when receiving is incorrect. That's the cause of the apparent contradiction.

> . .
> In transmit mode, the radials have a standing wave on them and provide the
> RF ground side by 'converting' the high voltage at open circuit end to a low

Unfortunately, your concept of how the antenna works when transmitting is also incorrect. The radials are just as much a part of the antenna system as the "antenna". Their symmetry results in their total radiated field being much smaller than that from the "antenna". The notion of an "RF ground" in space is simply a matter of your imagination; no such thing exists.

> Do the radials have a standing wave on them in receive mode?

Yes. So does the vertical. And both do in transmit mode also.

> Does antenna
> reciprocity theorem agree that the antenna can form same feedpoint impedance
> and field pattern in both transmit mode and receive mode, even though the
> electromagnetic field works differently?

The impedance is the same for transmitting and receiving. The electromagnetic field does not work differently.

> Are the electromagnetic field
> patterns noticeably different according to whether antenna is receiving or

> transmitting?

No. They are the same. This is part of what is known as reciprocity.

> The vertical element is always known as the radiating element.

The antenna doesn't know or care what you call the parts. If the radials lie in the same plane, they radiate very little. If bent down, say, as is often done with a ground plane, they radiate a very substantial amount. What you call or "know" the various parts of an antenna as doesn't make any difference in how they operate. All conductors behave the same with respect to currents and fields, regardless of how you've positioned them or what you call them.

NO THEY DON'T! the traveling waves do not interact! Your measurement of
the superimposed voltages or currents makes you THINK they interact, but you
are just fooling yourself.

note, the superposition theorem says basically that the response of a linear
network to several input signals can be represented as the sum of the
responses of the individual signals. it says nothing about being able to
take apart a signal to regain the separate inputs once you have added them
together.

i.e. suppose you have a linear system f() and feed it with signals x(t) and
y(t). the superposition theorem says:
f(x(t)+y(t))=f(x(t))+f(y(t))

so lets say the function 'f' just doubles the input voltage. and to make it
really simple assume x(t) and y(t) are just constant values x and y. now
answer the following question using superposition:

Given f(x+y)=4
And f(x)+f(y)=4
Find x and y (show your work)

Give up? Good for you! now you understand that knowing the sum does NOT
tell you the components, even in a very simple linear system.

I think you would agree the field pattern the antenna sees from a distant source is different than the field pattern the antenna generates on transmit. The field is uniform about the vertical axis on transmit and the phase of the signal in each radial is identical. But on receive the phase of the induced signal is unique into each radial.

This difference has nothing to do with reciprocity of course, but noting the differences between a unidirectional field pattern versus an omnidirectional one might help to clarify the apparent assymetry between receive and transmit.

Dave, just to be clear, here's the list I added to.

1. Darwin was a tool of the Devil.
2. The Earth is flat.
3. Faith can heal all disease.
4. The Earth is 6000 years old.
5. Forward waves and reverse waves interact to form standing waves.

It is a list of foolish absurd notions - so I agree with you.

Hi Jim,

What you describe about the asymmetry of response to a distant source
is all perfectly true (and offers a similar argument in regards to
placing a 3D antenna into 2D null space).

However, your conclusion that there is a difference in field patterns
does not follow. Such patterns infer a multiplicity of loads for
transmit; or, in this case, a multiplicity of sources for receive.
These loads/sources populate a spherical constellation of constant
radius to exhibit the patterns we see in models. Two points do not
render a pattern.

For a one transmit source, one receive antenna, the receive antenna
current asymmetry will ALWAYS be oriented towards the source
regardless of where it is. As long as either moves in a constant
radius, the asymmetry will always follow the shared the axis. Add a
second source, and the receive antenna will similarly develop the same
axial/asymmetry relationship. The net contribution of a constellation
of sources will simple average out the asymmetry back into the rather
pedestrian distribution pattern.

The impedance of an ideal current sink is always infinite,
whether it is conducting no current or any current. So the
first level model I proposed above aligns with your
statement.

Certainly the model I described is linear. Is there some
other fault in the model that makes it sufficiently incorrect
to be unusable?

It has to. Thankfully, rotational speed is the one thing that does
not change between the radio and the antenna.

> How can that be when the forward current
> phasor and the reflected current phasor are rotating in opposite
> directions?

Rotational speed has nothing to do with direction of travel. It has
only to do with the source. Rotational speed is simply omega;
2pi*c/wavelength, or 2pi*f. When waves of equal frequency are
traveling in opposite directions, the RF waveform which comprises the
standing wave (the latter being simply the amplitude envelope of the
superposed traveling waves) has the same wavelength, and thus the same
rotational speed as the traveling waves. Although the position of the
peaks does not vary with time, their amplitude is still a time varying
function. This rudimentary effect is illustrated in the movie here:

http://www.kettering.edu/~drussell/Demos/superposition/superposition.html

Mixing on the other hand is the product (rather than the sum) of two
or more waveforms and does in fact yield different rotational speeds.

The reason I assumed that is this assertion by W7EL.
"This is the total current. It has magnitude and phase
like any other phasor, and the same rotational speed
as its components."

The total current, as graphed by Kraus and displayed
by EZNEC *DOES NOT* have the same rotational speed as
its components. It is obvious that Roy meant the
same direction when he said "same rotational speed".

You got it. Einstein said an explanation should be as simple as possible, but not too simple. There is too much evidence gathered over decades of arguments for simple-minded models to work anywhere except in your dreams.

Your earlier example proved it. In a source with absolute zero power, you claimed that all the reflected power was being dissipated in that source. Maybe you should fix your trivial model before tackling anything more complicated.

Jerry, it seems to me that the Cobra is a compromise, and we each make our own judgements about the trade-offs that are acceptable. Of course, those individual considerations make recomendations like "it works great for me, it is the best for you" rather worthless.

Some of the claims about some antennas (including the Cobra) seem unrealistic, but that doesn't condemn the antennas, it just means people building or buying them based on those claims have been mislead.

It is my view that understanding the behaviour of the antennas helps you to make an informed judgement about the trade-offs in your own situation, and it allows you to get the best out of the antenna as installed.

Modelling suggests that the Cobra Jnr has a couple of weaknesses, one is the spikes in loss at some frequencies (an artefact of linear loading), most but not all of which are outside amateur bands; and the second is that the "window" of low loss around 80m is narrow and might be worth checking that as installed, that window is centred over your most desirable operating frequncies. These effects scaled for the double size

are more pronounced with the full sized Cobra.

An effect similar to the second point above exists also with the G5RV, and I have suggested a procedure in-situ tuning for optimising 80m performance. If I had a full sized Cobra and intended using it on 160m, or a Cobra Jnr on 80m, I certainly would think about doing similar.

Tom Ring, K0TAR wrote: "I`ve always wondered how he managed to have "NO SIGNAL RESPONSE IN THIS PLANE" for yz though. "

I guessed that Arnold Bailey just assumed perfection in some instances for practical purposes. My own experience has been that differences of less than one dB were not to be confided in. Reg Edwards used to speak of "delusions of accuracy", and I think he grasped a lot of wisdom there.

Best regards, Richard Harrison, KB5WZI

Okay, so you can't find anything to point at that is wrong
with the model. You could always ask. I could point to a
few things that are arguably weak with the model.

Of course I claimed no such thing; you do need to read
more carefully. And you have conveniently neglected the
other example which was presented right beside for
which 4 times the "reflected power" was dissipated by
the source. These two copmletely different results
call into question the nature of "reflected power".

What is wrong with the model is that it doesn't work
in reality. Neither does the 6000 year old model of
the age of the earth.

No, they call into question the validity of the model.
The reflected energy is there and can be dissipated
by a circulator load. That the model gets it wrong is
proof of an invalid model, not proof that photons
contain zero energy. Photons contain energy that obeys
the conservation of energy principle.

The fact that zero energy is dissipated in a source
is prima facie evidence of destructive interference
and a "redistribution of energy in a direction that
allows constructive interference". Understanding
interference is the key and your model doesn't even
mention interference.

Hmmm. Having a complete inability to articulate any issues
with the model, you are, none-the-less, convinced that it does
not work in 'reality'. Hmmm.

But then what is the fact that 4 times the energy is
dissipated in the source prime facie evidence of?

Good explanations explain all the observations, not
just the supporting ones.

I'm still trying to decide on a ready-made HF antenna. I have a couple more questions.

Can the Barker & Williamson's BWD-90 really be used without an antenna tuner?

Does the G5RV really need an antenna tuner?

Wow, there's a 7:1 price difference here! Hope to be QSOing soon, instead of emailing.

I have been articulating issues with the model for weeks
now and I am just about articulated out. We are repeating
the same things over and over and unless you take time
out to comprehend interference, there's no reason to
continue.

>> The fact that zero energy is dissipated in a source
>> is prima facie evidence of destructive interference
>> and a "redistribution of energy in a direction that
>> allows constructive interference".
>
> But then what is the fact that 4 times the energy is
> dissipated in the source prime facie evidence of?

Of *total constructive interference* in the source, of
course. I already answered that question days ago. It
is futile to try to communicate with someone who refuses
to listen. Here are the power intensity equations
governing the power dissipated in the two sources in
the previous two examples.

Thevenin equivalent if P1 = P2:
Pdis = P1 + P2 - 2*SQRT(P1*P2) = 0
Total Destructive Interference as defined by Hecht in
"Optics", 4th edition, page 388.

Norton equivalent if P1 = P2:
Pdis = P1 + P2 + 2*SQRT(P1*P2) = 4*P1
Total Constructive Interference as defined by Hecht in
"Optics", 4th edition, page 388.

Until you learn to recognize interference when it is staring
you in the face, you are going to continue to make the same
mistakes over and over. Forward and reflected energy is alive
and well and obeys the conservation of energy principle. That
you cannot figure out where the photonic energy goes during
a wave interference event is not my problem. Hints about
destructive interference:

www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness
of the film are such that a phase difference exists between reflections
of p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be
zero."

Note that "intensity" is *power density* in watts/unit-area.

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all 'lost' reflected intensity will appear as
enhanced intensity in the transmitted beam. The sum of the reflected and
transmitted beam intensities is always equal to the incident intensity.
This important fact has been confirmed experimentally."

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index
.html

"... when two waves of equal amplitude and wavelength that are 180-
degrees out of phase with each other meet, they are not actually
annihilated. All of the photon energy present in these waves must
somehow be recovered or *redistributed in a new direction*, according to
the *law of energy conservation* ... Instead, upon meeting, the photons
are *redistributed to regions that permit constructive interference*, so
the effect should be considered as a *redistribution* of light waves and
photon energy rather than the spontaneous construction or destruction
of light."

emphasis mine

Any antenna can be equipped with a resistor that will
dissipate so much RF energy that a tuner is not required.
A dummy load will do the same thing. One review of the
BWD-90 says it is the biggest air-cooled dummy load in
the world.

Bob, check out www.cebik.com for an
anlysis of the B&W antennas, G5RV's and
others.

The B&W antenna radiates better than a
dummy load of course, but is less
efficient than alternative antennas
burdened by other constraints.

We haven't quite reached the "one size
fits all" stratum yet.

Cecil,

I heard a rumor that the FCC does not like people to inject class-C type pulses directly into an antenna from the output of an amateur transmitter.

Perhaps that rumor is just an urban legend, however, and non-linear outputs are welcome.

The subject is modeling a class-C source, Gene,
not filtering a class-C source. We all know how
to filter a class-C source. Do you have a model
for a class-C source?

From: Joey <joey@nowhere.org>
Message-ID: <dd64339h0kluu9d5kqu0tff6h9r6nmpbdl@4ax.com>
Source record: 42004

Hi,
I'm trying to determine if I could use 10 meters to contact a station about 75 miles away with about 2500ft elevation of a couple sets of hills in between with just simple antennas on either end. Perhaps a 10m dipole on one end and some kind of stealthy one on the other. I assume this would have to be ground wave only given the distance and current band conditions.
My parents are both techs so we're currrently limited to parts of 10m as the lowest band and I'd like to have something reliable without need repeaters for disaster comms. We actually only have a few single hop VHF/UHF repeaters between us, though quite a few linked ones.
I've also thought of 6m due to smaller antenna requirements, but I'm pretty sure this is too far...
Thanks!

Hi Joey,

That's hit number one, distance at this wavelength.

>with about 2500ft elevation of a couple sets of
>hills in between

That's hit number two with the terrain against you.

>with just simple antennas on either end.

That's hit number three, antennas without gain.

>Perhaps a
>10m dipole on one end and some kind of stealthy one on the other.

That's hit number four, every possibility of being cross polarized,
and with at least one antenna masked by building or foliage to qualify
as "stealthy."

>I
>assume this would have to be ground wave only given the distance and

You might try NVIS, but what you say, as follows, doesn't give you
many band options.

>My parents are both techs so we're currrently limited to parts of 10m
>as the lowest band

It's time to upgrade. Consult the new rule changes, take a practice
test, and see what happens.

>and I'd like to have something reliable without
>need repeaters for disaster comms.

Then you really need to stop rationalizing about having a "stealth"
antenna. If this was Hurricane Katrina, how long can you call CQ
under water?

I figured it was a long shot. By "stealth" i just mean something low
profile and the other end doesn't have much yard space and a big
verticle is certainly not going to be sticking up on top. I suppose I
could making something that's just deployable when needed since this
isn't for day to day use... seems upgrading may help....thx...

Cecil,

The original topic was the *output* of an amateur transceiver, e.g., as
seen by a transmission line.

Sorry I did not catch the thread redefinition toward the inner workings
of such a device. That move could open up infinite opportunity for more
arguments.

Good afternoon, Bob.

I agree with Chuck and Cecil. The B&Ws are radiating dummy loads, nothing more.

One time, I was on a 75-meter net with another station about 15 miles from me, and several other stations elsewhere in the state, as far as 150 miles away. The other station (the one 15 miles away) was running 100 watts and a B&W at 25 feet. I was running a grand total of FIVE (5) watts and a cut dipole at 20 feet. My 5 watts was reported as stronger than the other station's 100 watts.

I read another report in this newsgroup from another amateur who said pretty much the same thing except in his case it was a MARS net, I think, somewhere above the top end of 75 meters.

For the price of a B&W, or perhaps just a bit more, you can buy the materials to make an 80-meter dipole fed with ladder line, and an autotuner e.g. from LDG that will let you run that antenna on 80 through 10.

That's what I would recommend if you want easy and relatively inexpensive multiband operation.

Apology accepted. The crux of what we have been discussing
for days, if not weeks, is what does a model of the active,
dynamic volcano of energy, i.e. the source, look like?

Let's not overstate the case against the
B&W. Cebik's modeling shows a ~6 dB
penalty for the 90' B&W at 6 MHz and
above, while at 4 MHz, it is more like
12 dB, which is very roughly
commensurate with your anecdotal report.

Obviously, one does not endure such
losses without countervailing benefits
which, in this case, are superb
frequency agility, simplicity, and
reliability.

While I wouldn't own one, others do.

75 miles is a bad distance for 10M I have almost no cotacts at that range.
The few occured while doing mountain toping.. Great time to upgrade just get
online and keep taking practice test until you pass.

It's a matter of logic, Jim. We know that the forward
current and reflected current phasors are rotating in
opposite directions. Kraus and EZNEC say that the
phase angle of the current on a 1/2WL dipole changes
by only 2 degrees, end to end. Therefore, contrary to
what Roy asserted, the total current does NOT have the
same rotational speed as its components.

That was Roy's mistake in using total current to try
to measure phase shift through a coil. One cannot
use total current phase on a standing wave antenna
to determine any valid measurement concerning phase
shift through a coil. But since the phase information
is preserved in the total current amplitude, it can
be used to estimate phase shift through the coil.

Roy said, "What I measured was a 3.1% reduction in
magnitude from input to output, with no discernible
phase shift."

From this, for a base-loaded coil we can estimate the
phase shift through the coil to be

arccos(.969) = 14.3 degrees

With no discernible phase shift we can estimate that
there was no decrease in current from end to end for
either the forward current or reflected current.

75 miles is do-able, but stretching it on 10m..
#1, if using simple antennas, good elevated
verticals, or ground planes would be your
only chance. No way you are likely to make
it with horizontal dipoles. And to make 75
miles, the antennas really need to be fairly high.
The hills may be a problem..
Power would help...
If both stations had high ground planes, to talk
75 miles with any reliability, you really would
need an amp, doing 500+ watts on both ends...
There is no NVIS on 10m, unless you get the
fluke chance of backscatter, or aurora..
I've done both on 10m... Backscatter is not that
uncommon, but the aurora is not going to happen
too often. But I've used aurora propogation to work
stations a lot closer than usual.. Sounds like talking
through a window fan... The last time I did that was
in the late 80's at the solar cycle peak.
Anyway, talking 75 miles reliably on 10 can be done,
but most that do it run high verticals, or beams,
and most run power. Note CBers.. They do it all
the time.
But again, that hill may or may not be a problem..
What you might want to look at is 2m SSB using
beams.. But again, the hills... ??
Those will be more of a problem, the higher in freq
you go I bet. Maybe it's time to upgrade, and use a

freq more suited, like 40 in the day, and 75 at night..
Actually, 75m will work that distance most any time
of the day.
If you can't have at least a good vertical on 10m, it
ain't gonna happen. Where as a low stealth dipole
would work on the lower bands, using NVIS propo.
Also, no power is needed in most cases.. 100w
is more than enough. 10w is plenty in many cases.

I've been 'googling' for a MININEC-based antenna modeling program (or programs) and I've decided a guy could get old and grey before he was through looking at all the offerings. I've kind of (based on web page descriptions) compiled a short list of candidates as follows:

MMANA by JH3HHT
EZNEC by W7EL
NEC-Win Pro by Nitanny Scientific

Is anyone here using any of those, especially NEC-Win Plus? Can anyone recommend one that they KNOW is better than the ones on my list? I have $450 budgeted for this but I might consider something a little costlier if it were overwhelmingly better.

The technical content of your posting is noted. Roy can
easily verify that EZNEC disagrees with his assertion
that "the total current has the same rotational speed
as its components". The total current has hardly any
rotational speed at all, i.e. 2 degrees of rotation
end-to-end in 180 degrees of a 1/2WL dipole.

EZNEC does not display "rotational speed". The user sets the rotational speed of all voltage, current, and field phasors by choosing the frequency, and it remains constant at that rate for all voltages, currents, and E and H fields. The "direction" of the rotation is always forward in time; it does not stop in time nor reverse and go backward in time. This should be obvious to anyone who has taken a beginning course in circuit analysis.

I'm bothering to respond to Cecil's rantings and diversions only because he's using EZNEC to support his junk science.

All voltages, currents, E and H fields reported by EZNEC have the same (phasor) "rotational speed", which is 2 * pi * f radians/second where f is the frequency chosen by the user. Nothing which EZNEC reports alters this. The fact that the phase angle of the current is nearly constant over the length of a dipole indicates that the phase angles of the elements of current along the wire are nearly the same. This means only that at any instant, the phasors representing currents along the line are all pointing in nearly the same direction. All are rotating at exactly the speed given above.

If one wants to break the current into "components", that is, any number of currents which linearly sum to produce the total current, the phasors representing all those components will also rotate at the same rate.

I'd suggest that Cecil go back and review basic phasor theory, but I know that learning isn't the objective here. It's to sustain the argument at all costs and any level of banality until everyone else tires and leaves.

EZNEC has a free demo. I compared that against what I could glean from the advertising info of the other candidates. EZNEC allows me to think about antennas while I am using it rather than think about programming.

EZNEC has saved me a lot of labor with my "antenna habit". EZNEC and Nittany Scientific products are used in the ARRL antenna course. That course is a good value as well.

Hey, are you guys using a non-standard definition for "phasor"? I'm
really confused by Jim's posting here. To me, a phasor simply
indicates the amplitude and phase of a sinusoidal component, relative
to some reference phase. I'd be comfortable with a "local definition"
that said the amplitude was relative to a reference amplitude, or was
in dB or dBm or dBuV or the like. But I am NOT comfortable with the
idea that a phasor at a particular point in space rotates in time
unless there is some time-varying thing that causes it to rotate,
maybe like a "trombone" section of line that someone is sliding in and
out. I do expect the phasor that represents a sinusoid propagating on
a transmission line to be a function of distance along the line and of
the frequency of the signal, in that it must rotate 360 degrees for
every one wavelength along the line. (More detail on this below.)

For "phasor" to be a useful concept, you'd better be talking about a
system in which there is a single sinusoidal excitation frequency --

or you better be verrrry careful to define what you mean by your phasor diagrams.

See, for example, the page in Wikipedia on phasors.

Or else please give me enough info or references so I can straighten out my thinking about them.

If I'm not mistaken, on a lossless line excited by a source at one end with a reflective load at the far end such that the amplitude of the forward wave is a1 and the amplitude of the reflected is a2, then the phasor representing the forward wave, relative to the source end, will be
forward phasor = a1*exp(-jx/lambda)
and for the reverse, assuming for convenience that the line is just the right length so that the reverse is in phase with the generator at the generator end,
reverse phasor = a2*exp(+jx/lambda)
where x is the distance along the line from the generator, lambda is the wavelenth in the line, and exp() is e to the power(). Then the phasor of the whole signal, fwd plus refl, at any point x is
net phasor = a1*exp(-jx/lambda)+a2*exp(+jx/lambda)
exp(jy) can be expanded as cos(y)+j*sin(y), so
net phasor = (a1+a2)*cos(x/lambda)+j*(a2-a1)*sin(x/lambda)

This makes is VERY clear that the phasor changes angle along any line where a2 does not equal a1; in the special case where a2=a1, then the phase can only be 0 or 180 degrees all along the line. If you pick a different reference point (e.g. change the load or line lenght or frequency in a way that moves the generator away from a point where the return is in phase with the generator at the generator), then that just adds a constant phase offset. But also notice that if a2 does not equal a1, the phasor angle along the line goes through all possible values, zero to 360 degrees. If a2 is almost equal to a1, that phase shift occurs relatively quickly along the line, centered on points where cos(x/lambda) goes to zero. I expect the same to be true on a resonant antenna; the reflected wave is NOT the same amplitude as the forward, but is similar, so you'll find places where the phase change is quick but continuous as you move along the wire--this assumes that the antenna is long enough that you can find such places.

Cheers,
Tom

Cecil,

In the context of antenna and transmission line matters you have an interesting definition of "source" for an amateur transmitter. Why consider the source to be some place after the output conditioning, such as the output connector, when you can go all the way back to the wall plug?

Hi RDW

It cant hurt anything to study the ARRL course. But, EZNEC is so logical
that you can do alot of modeling without having done any "course studying".
It is a very 'user friendly' program.
There are guys on this net who can be Very helpful with answering any
questions about EZNEC. I didnt bother with the Free EZNEC. I bought the
program and began modeling the first day. A couple r.r.a.a. regulars
helped me learn the additional methods I wanted to use.

Joey wrote:
"My parents are both techs so we`re currently limited to parts of 10m as the lowest band and I`d like to have something available without needing repeaters for disaster comms."

I`d like a million dollars too!

75 miles is reliably unlikely without a line of sight path between radios at VHF unless expensive techniques are used.

A repeater located between the radios makes success much more likely. Examine the ARRL "Repeater Directory" and borrow a hand-held (likely for 2-meters) and see which repeaters you can call up from both ends of the path you would like to work. You will probably find you are in-business but not for profit as it is amateur radio. For back up in emergencies, you can use your cell phone or a wired phone.

Gene, W4SZ wrote:
"Why consider the source to be some place after the output conditioning, such as the output connector, when one can go all the way back to the wall plug?"

The wall plug can scarcely be responsible for harmonics on the trabsmission line and antenna, but the output conditionimg can be inadequate.

A tank circuit of reasonable Q can be adequate to remove enough harmonics to make the transmitter a linear source in many cases.

A linear source makes King, Mimno, and Wing`s statement on page 44 of "Transmission lines, Antennas, and Wave Guides" operative:
"When impedances are conjugately-matched for transmission of power in one direction, they are conjugately-matched for rower transmission in the reverse direction, if no power loss occurs in the matching devices."

Hi,

If EZNEC reports a source impedance for a balanced antenna, such as a loop, of R+-jX ohms, and I am trying to match the antenna to the line: I am using a Smith Chart program that is unbalanced i.e. everything is respect to ground. Question is, what impedance do I enter into the program such that I will get the correct matching solution for the balanced antenna? I have used this program numerous times and it works well for verticals, mobiles, and other unbalanced antennas. Thanks.

5218. Re: Rotational speed

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-27 22:37:16 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <1334up0tkm8j3fc@corp.supernews.com>
Source record: 42084

A phasor is a replacement of cos(omega * t + phi) with cos(omega * t + phi) + j * sin(omega * t + phi) = exp(j * (omega * t + phi)) = exp(j * omega * t) * exp(j * phi). The first of those quantities is understood but not generally written in phasor analysis, but is nonetheless an essential part of the definition of a phasor. This shows that a phasor is a vector which rotates in the complex plane, with a rotational speed of omega * t radians/sec. The reason the time-dependent rotational term is left out when speaking of phasors is that phasor analysis is used only for systems in which only one frequency is present, as you said. Therefore, all have the identical multiplying term exp(j * omega * t) and, basically, they all cancel out in phasor equations. Omega is, of course, 2 * pi * f.

Cecil regularly confuses the change in phase angle of the phasor with position, with the rotation of the phasor with time.

A proof of the validity of the replacement of the real cos function with the complex phasor function, as well as a good description of phasors in general, is given in Pearson and Maler, _Introductory Circuit Analysis_. A good graphical illustration and description of a phasor as a rotating vector can be found in Van Valkenburg, _Network Analysis_. Those are the only two basic circuit analysis texts I have, but I'm sure the topic is covered well in just about any other one.

Hi Gary

Is it practical for you to use a Smith Chart rather than a "Smith Chart
program"? A Smith Chart doesnt concern itself with ground. It is mearly
a plot of all possible R+/-jX with real R.

Jerry

Even if you don't buy the ARRL Antenna course, you can buy the $39.95 "ARRL Antenna Book" which comes with a customized version of EZNec with models of every antenna discussed in the book.

I started with EZNEC using the customized (and somewhat crippled) ARRL version, but the program was essentially free with the ARRL book. When I decided that I wanted to model my own designs and save the modifications that I made to existing ARRL files, I bought the full program (which can still open and manipulate all the ARRL models).

Gary,

The impedance transformation is unaffected by whether the load is balanced or unbalanced. The Smith chart solution does not depend on balance or not, nor does the underlying maths.

Having said that, if you intend including a balun, you could treat it simply as an ideal n:1 impedance ratio transformer, dividing the load impedance at the appropriate point by n... though that may splitting your Smith chart solution into two parts each side of the transformer (if n!= 1). Some Smith chart software allows specification of a transformer as a system element, so it is real easy and all displayed on one map.

If you don't want to treat the balun as ideal, my view is that you really need to include the balun and a path for common mode currents in your NEC model, because they are actually couped to the radiator and form part of the system load.

Owen

The impedances will still be the same. If you want to keep things balanced, though, split any series elements into two equal parts. For example, if your program says to use 20pF in series, use 2 40pF caps, one on each side, to keep things balanced. With an inductance, use two inductors that are half as large as the single one. The idea is the two caps in series or the two inductors in series make the specified net capacitance or inductance. With shunt elements, there's no need to do that, just don't ground either side---the shunt elements go across the balanced network from one side to the other.

Cheers,
Tom

Roy Lewallen wrote:
> EZNEC does not display "rotational speed". The user sets the rotational
> speed of all voltage, current, and field phasors by choosing the
> frequency, and it remains constant at that rate for all voltages,
> currents, ...

Sorry, that is not true for *total* current. Check it out
yourself. EZNEC says the phase of the total current only
varies ~3 degrees from end to end for a 1/2WL dipole.
Kraus agrees with that.

Here's what you said: "This is the total current. It has
magnitude and phase like any other phasor, and the same
rotational speed as its components."

That is simply a false statement. And because it is
false, your current phase measurements through a loading
coil were invalid. Here's what you said:

"What I measured was a 3.1% reduction in magnitude from input to output,
with no discernible phase shift."

Of course you measured no discernible phase shift since
you were using a current that doesn't change phase. The
current that you used gives us no clue as to the phase
delay through a loading coil.

The phase of the total current is naturally related to
the rotational speed and it is almost unchanging, i.e.
the total current doesn't rotate by more than ~3 degrees.
It certainly does NOT rotate at omega*t.

That is one thing that makes standing-wave current quite
different from traveling wave current. You used standing
wave current to try to measure the phase shift through
a loading coil. Since standing wave current doesn't change
phase by more than ~3 degrees along the entire length of
a 1/2WL dipole, using it to "measure" the phase shift
through a loading coil is invalid.

The reason that the total current phasor doesn't have the
same rotational speed as the forward and reflected currents
is that it is the sum of the forward and reflected currents
which are rotating in opposite directions. The two phase angles
add up to almost zero all along a 1/2WL dipole.

OK, noted, but your definition doesn't match what I was taught and
what is in the Wikipedia definition at http://en.wikipedia.org/wiki/Phasor_(electronics).
What I was taught, and what I see at that URL, is that the PHASOR is
ONLY the representation of phase and amplitude--that is, ONLY the
A*exp(j*phi). To me, what you guys are calling a phasor is just a
rotating vector describing the whole signal. To me, the value of
using a phasor representation is that it takes time out of the
picture. See also http://people.clarkson.edu/~svoboda/eta/phasors/Phasor10.html,
which defines the phasor very clearly as NOT being a function of time
(assuming things are in steady-state). But in my online search, I
also find other sites that, although they don't bother to actually
define the phasor, show it as a rotating vector. Grrrr. I'll try to
remember to check the couple of books I have that would talk about
phasors to see if I'm misrepresenting them, but I'm pretty sure they
are equally explicit in defining a phasor as a representation of ONLY
the phase and magnitude of the sinusoidal signal, and NOT as a vector
that rotates synchronously with the sinewave.

Cheers,
Tom

This is false!!! Set a zero load anywhere along a 1/2WL dipole
and check the phase. It will everywhere be within 3 degrees of
zero.

> Nothing which EZNEC reports alters
> this. The fact that the phase angle of the current is nearly constant

> exactly the speed given above.

This contradicts what you said before. You said the *total current*
phasor is rotating. Both Kraus and EZNEC disagree with you. Here's
what you said:

Roy wrote:
"This is the total current. It has magnitude and phase
like any other phasor, and the same rotational speed
as its components."

This is a false statement! And since it is false, it renders
your loading coil phase measurements invalid. The total current
does NOT have the same rotational speed as its components.
The phase of the total current does NOT change through a
loading coil or through a 1/2WL wire.

Should that be ...of omega radians/sec..., omega*t is the phase
displacement, omega is the phase velocity?

Tom,

I'm sure a lot of people forget the derivation of a phasor after using it for a while, just as they do so many other things.

Again, a phasor is a complex representation of a real sinusoidal function and, as such, definitely has a time varying component. That the component isn't written doesn't mean it's not there. By all means, check your texts. I'm sure that any decent circuit analysis text has a serviceable development of the subject.

I always cringe when I see wikipedia quoted as a reference -- I was referred to an entry regarding transmission lines some time ago, and it contained some pretty major misconceptions. That leads me to mistrust it when looking up a topic which I don't have a good grasp of. I don't have a full understanding of the process by which it's written, but it seems that all participants in this newsgroup are equally qualified to create or modify a wikipedia entry. How could that result in a reliable reference?

On a 1/2WL standing wave antenna, the reflected current is
within about 10% of the forward current. I think you will
find that under those conditions, the phase change is NOT
continuous.

The total antenna current reported by EZNEC is the sum of
the forward current and reflected current all up and down
a 1/2WL dipole. With the feedpoint as the 0 deg reference,
EZNEC reports only ~3 degree change between the feedpoint
and the end segment of the dipole. The phase change is
NOT quick and never exceeds ~3 degrees.

A typical forward current at the feedpoint might be
1A @ 0 deg while the reflected current might be
0.9A @ 0 deg. That phase angle is obviously zero.

45 degrees out from the feedpoint, the forward current
might be 0.975A @ -45 deg. The reflected current might
be 0.925A @ 45 deg. Adding those two phasors gives a
phase angle very close to zero. The phase angle does
NOT change quickly - it changes hardly at all.

Kraus agrees. On page 464 of "Antennas for all Applications",
3rd edition, Figure 14-2, he graphs the amplitude and phase
of the current in a 1/2WL dipole. The current phase never
exceeds ~3 degrees over the entire length of the dipole.
The phase change is NOT quick. It is exceedingly slow.

This has to do with how the forward current phasor and the
reflected current phasor adding together to obtain a *constant*
zero degrees of phase in a thin-wire dipole. Kraus shows
both a thin-wire dipole and a dipole where the length to
diameter ratio is 75. The length to diameter ratio of a
75m dipole is in the many thousands, closer to a thin
wire than to 75.

My recollection is of being introduced to phasors with the study of
electric machines which have real rotating magnetic fields. By
jumping onto the rotor and rotating with those magnetic fields,
solutions became trivial by allowing vector arithmetic on the now
stationary phasors.

Everyone is wrong except you, huh? The fact still remains
that your following assertion was wrong:

Roy said:
"This is the total current. It has magnitude and phase
like any other phasor, and the same rotational speed
as its components."

Total current on a standing-wave antenna does NOT have
the same rotational speed as its components. It hardly
rotates at all up and down the entire 1/2WL dipole.
EZNEC and Kraus agree with me on that fact. All you
have to do is fire up EZNEC and prove it to yourself.

That means that your and Tom's phase measurements
through a loading coil were invalid. One cannot
use a current with unchanging phase to measure
a phase shift.

This brings up a point that I need to clarify. All my phasors
are referenced to a phase angle of zero at the feedpoint. Take
a snapshot when the feedpoint phasor is at zero degrees and
then look at all the other phasors up and down the antenna.
I hope that clears up any confusion I may have generated by
not explaining my reference point earlier.

A most excellent description! Thanks for sharing it.

Now if we could just get a certain individual to either stay on the rotor or the stator and not keep jumping back and forth without telling anyone or even realizing it himself. . .

This is, of course, referenced to the feedpoint signal
at zero degrees. The phase of a traveling wave changes
45 degrees in 45 degrees of wire. The phase of the
standing wave changes no more than a couple of degrees
in 45 degrees of wire. Sorry for any confusion that
might have occurred because I neglected to explain my
reference phasor.

Roy Lewallen wrote:
> Now if we could just get a certain individual to either stay on the
> rotor or the stator and not keep jumping back and forth without telling
> anyone or even realizing it himself. . .

I apologize for any confusion I may have created. All of my
phasors are referenced to the feedpoint current at zero
degrees, which is what EZNEC does.

If the feedpoint forward current is at zero degrees, the
forward current 45 degrees away will lag by 45 deg.
The reflected current 45 degrees away will lead by 45 deg.
The forward current 90 degrees away will lag by 90 deg.
The reflected current 90 degrees away will lead by 90 deg.
Thus the forward current and reflected current phasors
are rotating compared to the feedpoint reference.

The standing wave current phase, referenced to the feedpoint
phase, changes hardly at all. The standing wave current
phase is essentially the same all up and down the dipole.
The standing wave current phase is essentially the same at
the bottom and top of a loading coil. The standing wave
current phase is essentially unrelated to the position
on the antenna or loading coil. Standing wave current
cannot be used to determine the phase shift through
a loading coil.

Well, we used to have one waaay back in Non-linear Transistor Design.
Done with harmonics and relatively simple math as I remember. Gave
remarkably accurate answers only using the fundamental plus 2 or 3 of
them. The course was mostly about tank circuits, doublers, triplers,
PLLs, etc. though, since the non-linear stuff was so easy once learned.

Of course it wasn't really a model of a class-C source, since it
actually did anything you could think of. So I guess it wouldn't qualify.

Sorry I mentioned the concept.

Isn't hopping onto the rotor (assuming synchronous speed) to make your
observations called moving from the time domain to the frequency domain,
and all the mathematical shortcuts are only valid if all quantities share
the same angular velocity (or frequency), implying sinusoidal waveform.

I guess a departure from the strict phasor environment is for example
when we consider a noise vector rotating about the end of a carrier
phasor in exploring FM detector S/N vs C/N.

Hi Roy,

Well, I did not forget the derivation. In Balabanian, "Fundamentals of Circuit Theory," (a book I have but didn't actually study from) he uses "sinor" instead of "phasor" but says they are the same, then in a convoluted way gets around to saying that it's just the phase and magnitude, and not the real(exp(jwt)) part. Smith, "Circuits, Devices, and Systems," (most likely the book from which I learned about phasors) is much clearer about it. Under "Phasor Representation" in my edition,

"If an instantaneous voltage is described by a sinusoidal function of time such as
v(t) = V cos (wt + theta)
then v(t) can be interpreted as the "real part of" a complex function or
v(t) = Re {V exp[j*(wt + theta)]} = Re
{[V*exp(j*theta)]*[exp(j*wt)]} (eqn 3-18)
In the second form of eqn 3-18, the complex function in braces is separated into two parts; the first is a complex constant, the second is a function of tiem which implies rotation in the complex plane. The FIRST PART we DEFINE [Tom's emphasis...] as the phasor (bold) V (/bold), where
(bold) V (/bold) = V*exp(j*theta)
...
The phasor V is called a "transform" of the voltage v(t); it is obtained by transforming a function fo time into a complex constant which retains the essential information. ... "

OK, so your definition is different from mine. So far, I've found two actual definitions of the phasor on-line, and both agree with my books and my own useage. But if it's common useage to consider a phasor to be a rotating vector, I'll defer to that at least in this discussion. So far, though, I haven't found a reason to give up my definition of a phasor. ;-)

Cheers,
Tom

2m SSB or CW with modest power and antennas have a great chance of doing what you wish.

A better description of the terrain would help.

2500 above mean average terrain? (I doubt that but have to ask)

A couple of hills. Sharp ridges? Above the line of sight?

Probably still quite doable. I used to work from Potsdam NY to Plattsburgh NY (and a good chunk of Vermont) virtually every evening on 144.200 with a 12 foot yagi at 25 feet on my end, a 17 foot on the other, using about 60 watts, and the Tug Hill Plateau and a couple small mountains in the way.

2m "weak signal" is an often overlooked mode for 60 to 150 miles that is very reliable for point to point.

That's why it's essential to not forget the implied exp(j * omega * t) term -- all waveforms in an analysis must include it, and it must be the same omega for all. In addition to inherently non-sinusoidal waveforms, waveforms resulting from any nonlinear operation, such as frequency modulation or multiplying or squaring waveforms, can't be analyzed in that environment.

I find it's convenient to think of a phasor as rotating with respect to some other frequency, or stationary when you want to show the phase relation at some specific frequency in a circuit with complex impedances.

For example, if you are discussing the phase relations in AM modulation, you can set the carrier as a vector pointing to the right, and the upper and lower sidebands rotating in opposite directions with their centers on the end of the carrier vector.

The sidebands each have one half the amplitude of the carrier, so when they are aligned in the same direction as the carrier, the resulting vector is twice the amplitude, or length. When they oppose the carrier, the result is zero amplitude.

So a phasor can be stationary or rotating depending on its relation to something else in the discussion.

I am not sure it is that; more like rotating the frame of reference to
stabilize the view (or a stroboscope perhaps?). The time domain is
now captured in the notation on the diagram that says it is all
happening
at 60 Hz, for example.

> and all the mathematical shortcuts are only valid if all quantities share
> the same angular velocity (or frequency), implying sinusoidal waveform.

But I agree with this. If everything is not rotating with the same
velocity
(and not just frequency), then it is difficult to find a useful frame
of reference
to rotate.

Which suggests that if there are two directions of rotation, phasors
don't help much with the solution.

Clockwise, of course, by convention. Always look at the end of the
machine that lets you draw your phasor diagram clockwise.

This way, when a first phasor is clockwise from a second, the first
phasor occurs first when you convert back to time.

By conventional definition, coherent phasors traveling
in opposite directions are rotating in different
directions, one clockwise and one counter-clockwise.

Adding a forward wave and a reflected wave of equal
amplitude results in:

E = Eot[sin(kx+wt) + sin(kx-wt)]

By convention, the forward +wt wave rotates counter-
clockwise as the angle increases in the + direction.

By convention, the reflected -wt wave rotates clockwise
as the angle increases in the - direction.

The standing wave equation becomes:

E(x,t) = 2*Eot*sin(kx)*cos(wt)

Which direction is the standing-wave phasor rotating?

The equation for a standing wave,

E(x,t) = 2*Eot*sin(kx)*cos(wt)

would have an identical value if it were written,

E(x,t) = 2*Eot*sin(kx)*cos(-wt)

Thus, a standing wave phasor can be considered to be
rotating either clockwise or counter-clockwise.

Joey,

You have given a lot of information, and yet too little.

The distance you nominate can be a challenge, yet routinely possible on frequencies from 28MHz to 440MHz, depending....

My thoughts are that simplex contacts will be unlikely without effective outside antennas, though not necessarily directional antennas, but they would help.

You note you may have access to several repeaters, than can certainly equalise bad locations or impossible paths (eg granite), but then you might not want to conduct family chat on repeaters (though that is they way they seem to have gone here since many of our new six hour hams with their shack on their belt seem to be family members). An FM repeater in a very good location may support contacts reliably out to 150+km for each station, depending...

Another possibility might be using IRLP build a path.

To give you an example, I can work the 2m repeater at Mt Ginini (exceptional site) from the car on my driveway here at Narooma, 155km (~95mi) over mountains etc (but we don't have real mountains here do we?), it would be easier with a 5dB gain omni on the house.

I could use a handheld to make the trip to a repeater 90km (~56mi) away and use IRLP to anywhere in the world (if I liked IRLP). Then by

contrast, there would be places where you couldn't work a repeater 10km away with a handheld.

So, it may be that a path via a VHF or UHF repeater might be more viable than 10m.

Perhaps some experimentation is in order, that is what ham radio was about once.

It would, I think, be more precise to say that the vectors are
rotating. When you change your point of view by rotating
the frame of reference along with the vectors, those vectors
become phasors which do not rotate. Although a little
looseness in the language easily leads to saying that
they do.

I agree. I should have said counter-clockwise in my other
post. Once you jump on the rotor to rotate counter-
clockwise with the vectors, the rest of the world (e.g.
the stator) appears to be going clockwise around you.

I suggest that the solution to this ambiguity is to do the
same analysis for the current, which should be found to
be 90 degrees shifted from the voltage. The real current
is either leading or lagging the voltage. Rotate the frame
of reference in the direction that will cause a lagging
current to appear counter-clockwise from the voltage
and a leading current to appear clockwise from the
voltage.

This is all convention, of course. You can rotate the
frame of reference in either direction, you just need
to remember which direction on the graph represents
earlier time and which represents later.

Physically, it is just a question of which end of the
rotor you climb on to.

This just illustrates how artificial standing waves are.
For 1/4WL the standing-wave current leads the standing-
wave voltage by 90 degrees then suddenly undergoes a step
function to lag the standing-wave voltage by 90 degrees for
the next 1/4WL.

In any case, the point is whether standing-wave current can
be used to measure the phase shift through a loading coil.
EZNEC indicates that it cannot. Kraus indicates that it cannot.
Yet the people who did exactly that continue to report the
results as valid.

5261. Current in 1/2WL Dipoles

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-28 13:36:39 UTC
From: Cecil Moore <nospam@w5dxp.com>
Message-ID: <H5IYh.1645$tp5.306@newssvr23.news.prodigy.net>
Source record: 42027

The point I was trying to make on the "Rotational Speed"
thread got lost in semantics so here goes again.

Given - a 75m dipole modeled by EZNEC with 90 segments
in each leg of the dipole. 90 segments was chosen
to correspond to the number of degrees from the
feedpoint. Illustrating 1/2 of the dipole with
0 ohm loads at the following segments:

FP--------23--------46--------68--------90

EZNEC reports the following results:

Feedpoint current: 1 amp at 0 deg

Current at seg 23: 0.9281 amp at -1.06 deg

Current at seg 46: 0.7154 amp at -1.78 deg

Current at seg 68: 0.4049 amp at -2.31 deg

Current at seg 90: 0.0122 amp at -2.76 deg

Since the segment numbers correspond to the
number of degrees, it's obvious that the
segment numbers correspond to the expected
phase shift in the traveling waves.

Question: Assuming the current reported by
EZNEC is a ~cosine function, how does one use
that current to determine the traveling wave
phase shift in the wire?

Just off-hand, I would suspect for reliable and consistent
communications a three element yagi and ~100 watts on each end would
result in enjoyable rag chews ... same for 6m.

Height? More the better.

Seventy-five miles on omni antennas is very chancy, in my humble
opinion. But then, power/height would be the main variables, enough
height and power would certainly help.

Regards,
JS

More on this:

First, I agree with Mike's usage; if your phase reference is at one frequency and you're looking at a signal at a different frequency with respect to your reference, the phasor representing that different frequency will rotate at a rate equal to the difference in the frequencies: counterclockwise if the second frequency is higher, I suppose, since the second frequency's phase gets further and further ahead of the reference as time goes on.

Second, I did a google search for "phasor definition" and investigated a whole bunch of sites. Some didn't have anything worth noting. I made notes of 18 sites. Nine of them had strict mathematical definitions. Every one of the mathematical definitions agreed that a phasor contains only amplitude, and phase relative to a reference, and has the exp(wt) part stripped out. Some had a full development of the concept, and some only stated the end result, but in the result they all agreed. In the nine narrative definitions/descriptions, five were clear that a phasor contains only phase and amplitued and not time information--not a rotating vector with respect to time (unless it's representing a second frequency, presumably). Two of the narratives specifically said that a phasor is a time-rotating vector. The others were at best ambiguous, or simply didn't say.

To me, the whole idea of using phasors is to remove the time-varying quantity from discussion, so you can concentrate on phase and magnitude. As I showed in my first posting in this "subthread," phasors (as phase and magnitude only) very quickly lead you to an accurate description of what happens with forward and reflected waves on a transmission line, with respect to the amplitude and phase of the net signal at any point along the line. The phasor representation clearly shows that with waves of the same frequency of nearly equal amplitude in each direction, you get relatively long stretches along the line where the phase changes only slightly, and then a region where it changes very quickly. That's not something I can easily see in just thinking about the waves as time-varying quantites, but as phasors, the result is immediately obvious to me. There are plenty of other similar examples.

I'm very curious now to see exactly what Pearson & Maler and Van Valkenburg say in their texts. Are they clear with a mathematical definition, or do they end up just using words that can be interpreted in different ways? So far, I have investigated eleven references that define a phasor mathematically (the nine mentioned here plus the two college texts mentioned before), and all agree that it doesn't contain the exp(wt) component: in a linear system at steady-state excited by a single frequency, a phasor representing a quantity at a single point in space does not rotate.

I suppose I get a little carried away on things like this, but to me it's important that we're communicating with words for which we share a single definition, not words that mean distinctly different things to different people.

Cheers,
Tom

What is the current phase relative to. The feedpoint , the voltage in that segment? As I have read this thread there seems to be some confusion on this point.

It is very good information, provided you are dealing with cores of a known type. (#31 or #43) It would be nice if I had such material, and in the end I may have to resort to purchasing some. *SHOCK*

But as it is, I am looking at some cores that appear to be #35 material, and I cannot find any information as to how they react at freq. They most likely are not 'ideal for my purpose, but I am trying to determine if they can be used as 'close enough'. Either by adding more turns, or stacking more cores. But again, without a data sheet, or having one in hand to test manually this is rather difficult.

I believe that EZNEC references net current to the
source current of 1A at 0 degrees. I consider it
to be a *snapshot* of conditions when the source
current is 1A at 0 degrees. This is what I have

been assuming in all of my postings. I believe
that is also what Kraus does in his graphs.

Yes, that was what I was doing. I think that is what EZNEC
does. I think that is what Kraus does. It seems to be the
key in determining what phase shift occurs through a 75m
loading coil.

Incidentally, one of the best treatments of this subject,
IMO, is in "Optics", by Hecht.

> I suppose I get a little carried away on things like this, but to me

Apparently, someone needs to get carried away in order to
get this problem resolved. A measured zero phase shift
through a loading coil using a current that doesn't change
phase is meaningless and misleading.

Interesting question. I use AO program by Brian Beazely which is
Minninec based but Brian
has not supported that program in years. Based on that info I suspect
that could be classed now as freeware so a Google search may well
supply a user that is willing to provide a copy. Ofcourse you would
have to pursue the subject of legality for yourself before purchasing
tho I do not know how you would do that. I personally would love to
have the basic program
with all details to see if it could be remodelled but I have not heard
of anybody pursueing that avenue.

I do a lot of fiberglass work. Building a 335 MPH airplane. The two
most important points are the dust is quite hazardous which pretty
much mandates wearing a good mask and not the little disposable paper
or cloth ones. The filter needs to be very fine. As has already been
said, you want to keep the dust off you and your clothes. The other is
the dust is abrasive and you do not want it to spread. I use a "whole
shop" fan with a large filter set close to the work so the draft
carries the dust right into the filter. You also need to protect the
ways and moving parts on the lathe. Good bits have already been
discussed.

Remember that the resin is sensitive to UV light and unprotected with
degrade rapidly. Also the glass fibers are easily damaged by water
(which was a surprise to me) so the finished piece needs a good coat
of paint, or varnish to provided protection from both UV and moisture.

Thanks Roger, probably didnt do it right then, I used some old high speed
steel tools and duct taped the shop vac to the tool holder. I was just
cutting down a fibeglass rod join two pieces of Al tubing together. It
really dulled the heck out of the tool. but I got it done. I was thinking of
mixing up a little resin to seal the raw edges and give it a coat of
automotive acrylic enamel to finish it off. I work with fiberglass encased
antennas I find they wil last seemingly forever if you keep them painted.

Keep in mind that cores for chokes for suppression purposes need not and are usually not of low loss material. Often the materials used for suppression up to 500MHz might be quite lossy above 1MHz. Not only does that loss not prevent them being effective, it is the main mechanisme operating above typically 10 to 50 MHz. #43 is such a material.

I can't help you with characteristics of #35 material.

You might have to try to characterise it yourself, it isn't hard if you have access to an MFJ259B or the like (or better). It is easy enough, here is one I did for a part readily available in Australia: http://www.vk1od.net/balun/index.htm . BTW, these cores cost about A $35/metre whereas #43 cores of similar OD & ID cost about A$586/m (a 1600% price increas), or translated to a 300mm length for a balun, the Jaycar LF1258 costs A$10.50 vs T-37-43 for A$175. (I know that the #43 cores are much cheaper in the US.)

On Apr 28, 8:54 am, Cecil Moore <nos...@w5dxp.com> wrote:
> This just illustrates how artificial standing waves are.

You have hit the nail on the head here.

In another post you provided two expressions for the spatial
and temporal distribution of voltage on the line...

A) E(x,t) = Eot[sin(kx+wt) + sin(kx-wt)]
B) E(x,t) = 2*Eot*sin(kx)*cos(wt)

There are an infinite number. Three immediately come to mind...

C) E(x,t) = expressed as an exponental
D) E(x,t) = expressed as a differential equation
E) expression A) can be re-expressed as an infinite
sum keeping track of all the individual reflections.

All of these accurately yield the correct E(x,t) and there are
similar expressions which correctly yield I(x,t). In the same
sense that B) (called by you the standing wave expression) is
artificial, they are all equally artificial. And yet they each
have their place for solving problems since they all, in the end,
yield the correct E(x,t), the only thing that actually exists.

For reasons hard to fathom, you have latched on to A) as
being THE TRUTH, though it really lacks any features to
distinguish it from the rest. D) is arguably a much better
choice for truth since it will handle signals other than
sinusoidal.

As said before, you would find it valuable to let go of A) as
THE TRUTH, since it would permit you to solve real world
problems that you currently refuse to solve because you
believe the technique for solution conflicts with A) as
TRUTH.

Why is the answer to this question important?
Is it not the actual currents and voltages that are responsible
for radiation?

If I understand correctly, you are not disputing that the
actual currents in the wire show a small phase shift as
you move down the wire?

Sorry, Teh. I misunderstood your
original post. Somehow I thought you
already had the beads.

If you're looking for a great "how-to"
on the subject, including choosing
proper beads, take a look at this:

Because it holds the key to determining the phase delay
through a 75m mobile loading coil.

A) is easy to understand. The amplitude is where it needs
to be and the phase is where it needs to be to be properly
comprehended.

B) is what has everyone confused. The phase information
readily apparent in A) is embedded in the amplitude in
equation B). For a lot of people, comprehension has
disappeared.

Nothing is "clear" with respect to copyright. As with patents there
are rules that must be followed and the particulars of the particular
copyright has to be clear and approved which may not apply to the
subject as a whole. Even music moguls are finding it hard to control
copying and on top of that there are several exemptions with respect
to educational and libraries neither of which have been specifically
defined in changes by Congress in the latter part of the last century.
The antenna programmers also suffer from the fact that the general
routines were supplied by the government for general use which also
apply restrictions as to what specifically can be copyrighted. I
believe also that if a transfer is made via public E mail
can allow further reductions as to what is termed infringment. For
antenna programs I would assume that such a thing as an algorithm can
be copy righted but to try and cover all screen representations could
possibly be a nightmare. The bottom line is of course is that you are
copying something that was put together in some sort of ingenious way
then it is not yours to copy but people use the copy machines with
abandon so attorneys would have a field day with respect to expenses
in areas so murkey as copyright laws which is presently crippling the
music industry since infringment is enourmous and recompense for
violation is ridiculously small on a case by case basis. If a library
owns a copy and then makes another copy for patrons use you again get
into another murky area because that involves a exception area that is
not clear in substance.

I am quite sure that Brian Beazely "clearly" marked his product with
the necessary marks of intellectual property ownership.

>If a library owns a copy and then makes another copy for patrons use

That never happens in any reputable Library. They have absolutely no
interest in supporting piracy.

There is nothing murky about copying Brian Beazely's product and
distributing it. You are not going to get a pirated copy from any
Library.

Brian no longer sells antenna software to Amateur Radio customers for precisely Art's enlightened attitude. I alpha tested much of his software, and I am quite sure that even I couldn't get a copy of anything from him anymore. Nor would I try. He was royally screwed by our community. I don't blame him a bit for pulling out of our market.

I am also very thankful that we have Roy sticking around with an excellent product, and putting up with the slings and arrows and BS.

I remember being rude to another Tom, but I don't remember
being rude to you. I don't even remember your position.

Would you mind summarizing your crystal clear position on
how many degrees a 75m bugcatcher coil occupies in a resonant
mobile antenna?

Libraries have a specific exemption with respect to copyright laws and most libraries now have a CD library for its patrons. Same goes for enterprises that lease movies e.t.c..
Same goes for educational facilities and their faculty and pupils and as far as educational facilities go, even a ham radio club would qualify for that!. With all that being said I am not advocating piracy per se, I was ENQUIRING (not advocating) on the legitimacy of copying when a product is abandoned which in the case of a patent is done when a holder does not pay the regular maintenance fee required.and that include software patents.
On the other side of the coin one must remember we are talking about federal law which is an entity to itself in what laws it decides it wants to honor as well as the finances to do the job.. From a morality point of view piracy is wrong, from a reality point of view if a law cannot be enforced then it is a bad law because it is an example of laws that are seen that can be defied. I agree that Brians absence is a huge loss for the ham community but I am not fully aware of all the reasons tho I have heard rumours, but I remind you again I was enquiring about a properties standing in LAW when it was not only abandoned but also not for sale, plus the underlying principles being of the freeware type i.e. supplied by the Government free of charge.

> Are there any other loss issues missing in this example.

I would say you are close enough to say you are correct. Because you
chose a dipole which is in a state of equilibrium and thus particles
projected from the dipole cannot collide with other particles from
other parasitic radiators. Aren't you not basically refering to the
foundations of Poyntings vector which like Gauss is refering to an
item in equilibrium when subjected to a time variable of zero value ?
If the item is not in a state of equilibrium collision
of particles may well occur without a radiation field reaction thus
one cannot calculate the resultant field since energy transfer due to
particle collision prevents the return of particles to the mother
radiator.

Hmmmm. I would think that going to a frequency such as 144 MHz would be the way to go as radiation would tend to hug the earths surface.With 28 MHz the height factor not only be impracticable (point to point) but no amount of extra power is going to lower the TOA. When my son was in a hospital over 100 miles away he used his hand held to a local repeater and I used 10 watts with a directional antenna to the distant repeater with intervening land less than 100 foot elevation variance. Contact was always assured.

5291. Distributed capacitance effects Q?

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-29 04:32:18 UTC
From: Bill Bowden <wrongaddress@att.net>
Message-ID: <1177821138.653191.285430@u30g2000hsc.googlegroups.com>
Source record: 42057

Does anyone know why the distributed winding capacitance of a loop antenna, or any inductor, degrades the efficiency?

It would seem that a loop antenna with 100pF of winding capacitance in parallel with a external capacitor of 200pF would resonate at the same frequency as a antenna with no winding capacitance and a external capacitor of 300pF,but apparently that's not the case.

The best explanation I got was that winding capacitance represents 'low Q' and a external tuning capacitor represents ' High Q'

What is the difference between high and low Q, and why should a loop antenna with no winding capacitance perform any better than one with 50% of the total capacitance in the windings? Where is the energy loss?

Thanks,

-Bill

I have been on 10m myself lately, having just upgraded. I find it nearly worthless for anything over fifteen miles. Without skip, you need an elevated antenna, high ERP or both. 75 miles is inside the skip zone; that is, if 10 were going to skip, it is still overhead at 75 miles and is going to come down farther away.

Sure, investigate NVIS, but I think it needs a particular anntenna at *both* ends.

If you're not committed to 10m, I would recommend 2m, since at least one end can have a high gain antenna. I use a 13-element yagi for 2m at Field Day and I routinely work dozens of stations 75 miles away (or more). We are in southern San Diego County and I work Los Angeles all day and night on 35w with the yagi at 20 feet. 2m is almost noise-free, too, both with respect to QRM and to receiver noise in FM mode.

A couple of decades ago on 10 meters with a 3 element yagi and 100
watts, I frequently chatted with a grass valley station from a location
in calaveras county, a distance of over 75 miles as the crow flies (also
made a few contacts in San Francisco.) Antenna was 35 ft in the air and
the other guy in grass valley had a similar setup.

You never know, 'ya just never know ... but with two omni antennas, I
doubt it would have been done.

Now australia with an omni and a 100 watts? No problem with good sun spots!

5296. The Formula

Newsgroup: rec.radio.amateur.antenna

As an engineer, I have taken all the courses to make me as smart as I need to be, right? No, not a chance. Here I sit, stupified, not even knowing which variables to put in a formula.

To be found: How far will I get into a newsgroup thread before it degenerates into name calling, circular reasoning, begging the question, etc.

Maxwell never dreamed of this.

Hi Bill,

For the usual reasons: Resistance (not capacitance).

>It would seem that a loop antenna with 100pF of winding capacitance in
>parallel with a external capacitor of 200pF would resonate at the
>same frequency as a antenna with no winding capacitance and a external

It could be the case, your mileage may vary.

>The best explanation I got was that winding capacitance represents
>'low Q' and a external tuning capacitor represents ' High Q'

You got bum explanations then.

>What is the difference between high and low Q, and why should a loop
>antenna with no winding capacitance perform any better than one with
>50% of the total capacitance in the windings? Where is the energy
>loss?

It seems you may be, instead, writing about Unloaded and Loaded Q.
Loaded Q would be that found in service (in the actual application,
whatever that might be). Unloaded Q would be that found at the bench
with no other attachments. The Loaded Q's lower value is due to the R
of the "load" ...as it stands to reason. That load will be an
antenna's radiation resistance (and any Ohmic loss of the structure).

The energy loss is called radiation - if you do it right.

Hello Bill,

I assume that you mean radiation efficiency (ratio between actual
radiated power and total electrical input power).

I think inter-winding capacitance does not decrease efficiency, it may
only change the radiation pattern when the inter-winding capacitance
is that much, that the current distribution in the coil is affected.
This is almost the case with relative large loops.

When you have a loop close to a halve wave, just the own capacitance
is sufficient to get resonance (as with, for example, a halve wave
dipole).

Radiation efficiency may be reduced by losses in the insulation. When
windings are close together, the Electric Field strength in the
insulation can be that high, that loss becomes significant. This is
mostly the case when windings are touching.

Another thing can be corona discharge (that may in the end destroy
your insulation).

Best regards,

Wim

Hi Bill.
I agree with your assertion that distributed winding capacitance
degrades efficiency.
My thoughts about this are ;
Assume a 10 turn loop, between each turn there is a capacitance,
so, you have a complete circuit, (L,C,R) there is current
flowing through this circuit that is not flowing through the entire 10
turn loop. (this happens in the other 9 turns also)
I think these extra currents flowing that don't make the entire 10
turn circuit increase the losses.

Anyone care to run with that, or explain it more clearly, or shoot it
down.

Mike

The "100pF of winding capacitance" is NOT across the
entire coil as is the 200pF external capacitor. When
the operating frequency of a coil is more than ~15% of
the self-resonant frequency, the lumped circuit model
starts to fall apart. In your above example, the operating
frequency is ~60% of the self-resonant frequency so you
need to use the distributed network model (or Maxwell's
equations).

Quoting from an IEEE white paper about RF coils at:

http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

"... lumped element circuit theory does not (and cannot)
accurately embody a world of second order partial
differential equations in space and time."

"The concept of coil 'self-capacitance' is an attempt
to circumvent transmission line effects on small coils
when the current distribution begins to depart from
its DC behavior. The notion has been developed by
starting with Maxwell's equations and using only the
first two terms in the Taylor series expansion for
the distributed current to obtain an expression for
the self-impedance of a generalized closed circuit.
Upon extracting Neumann's formula for the self inductance,
the remaining negative component of the reactance permits
an expression for the coil self-capacitance. These formulae
are valid for a PARALLEL combination of an inductance and
a capacitance when the operating frequency is well below
1/SQRT(L*CL). They permit a coil with a SLIGHTLY
nonuniform current distribution to be treated AS THOUGH THE
CURRENT WERE UNIFORM and the coil was shunted with a lumped
element capacitance."

The author shows how to estimate the VF and Z0 of a coil
that is operated at more than 15% of its self-resonant
frequency. It can thus be modeled as a transmission line.

The same author shows in his class notes at:

http://www.ttr.com/corum/index.htm

that the calculated self-resonant frequency of a particular
coil based on the measured self-capacitance was in error
by 65.2% when the "lumped-element assumption" was used.

The calculated self-resonant frequency based on the
transmission line distributed network model was within
5% of the measured self-resonant frequency.

Hi Mike,

Capacitance does not bring loss. Loss ALWAYS resides in Resistance
and nothing else.

Between you and Bill, there appears to be a fixation on the loopS
(emphasis on there being more than one). If you are going to blame
them (that emphasis on there being more than one), and try to tie it
to loss (that emphasis being naturally in Resistance, not
Capacitance); then it follows it is in the natural increase in
conductor Resistance that occurs when wires are spaced closer than 3
or 4 wire diameters to each other. When wires (or loops in this case)
are in close proximity, the magnetic field of the near wire (or loop
in this case, and each loop in proximity to the next) FORCES the
current in that loop to the surface of the wire - INCREASING that
conductor's Skin Resistance. Loss thus increases by proximity.
Capacitance does too, but that is merely a correlating factor.
Remember (and this is good advice, especially suited to Newsgroup
rumors you may pick up): Correlation is NOT causality.

Maybe if you put this in a word blender and spun long enough, maybe you
could get one sentence that would make some sense. :-)
I gave up way back when I could not understand what is the POLARITY in
antennas, which end up? So I guess humanity has to evolve for few more
centuries to catch up with "antenna wizard" and understand and appreciate
his piosneering work.
Judging by some other posts on other more earthly subjects, looks like there
are some missing gears in the gear box. What you expect from inventor that
has a patent on reflector beeing director and vice-voica. Looks like that
one will not ever be copyright violated. So take it with grain of salt and
enjoy the mumbo-jumbo-entoitenmeint. :-)

Mike, you must first understand that that two unlike particles in
combination from the same radiator creates radiation. Lock that into
your mind. Other collisions or combinations do not creat radiation so
their energy has to be ascertained so they do not finish up on the
radiation side of the equation. If the radiating article is in
equilibrium there is no other radiator in competition in the same
space to create radiation thus the single radiator is free to emit
particles in isolation where errent collisions or combinations can not
occur. You must also note that all particles emitted from a single
radiator do not all finish up on the radiation side of the equation
since some return to the mother element with the same kinetic impact
that was imparted on them in the first place and thus these must be
accounted for in any equation. If one is to ascertain the final
arrangement of any energy transfer from a black box it is desirable
not to introduce energy exchange phenomina by introducing rival or
cumulative exchanges which cannot be accounted for. All equations that
do not allow for the unit of time are purely mathematical exercises of
theory thus one must be absolutely sure that the numbers add up on
both sides of the equation to justify the addition of that very
important symbol called equal. That is why the subject of ther terms

of "time" and "equilibrium" is important to transform an equation from a fantasy form to one of reality in both Poyntings vector and the Gaussian equation.

Equi Librium is a drug, that is too big to swallow, so you have to
crush it into particles on one mother of a radiator. If you try to
swallow it whole, you will get one massive field reaction (a buzz) in
a time variable of zero value (like really fast) which may induce
projectile vomiting.

Maybe.

If not, then we will have to Gauss again.

I don't know which patent you are refering to but I will examine your particular statement.
Length alone is not an indication of reflective or atractive atributes especially when viewed in combination of nearby elements. When elements are in close association it is the cumulative effect that determines whether it attracts or repels action from the driven element and where the increased diametrical action of two intertwined parasitic elements come to the fore. Knowing that english is not your first language I must point out to you that the term reflector and director are names applied to the function of a parasitic and not necessarily a
physical description of length.

Hello, Cecil,

Yes you are right, as soon as electric flux is leaking via inter
winding capacitance, the current distribution is no longer uniform.

Maybe Bill can find more info when searching for Tesla coil inductors.
I made a small one myself (H-bridge, running at about 700 kHz, [yes, I
know it is in the AM broadcast band]). The vertical coil behaves
almost as a quarter wave resonator, just a small top capacitor was
necessary.

Best regards and thanks for the correction.

I'm not ready to give on that yet, but I could be convinced.
It seems I could add capacitors across turns of a coil and increase
circulating currents that would show as a lower Q. But I haven't
built a coil to test this.

>Loss ALWAYS resides in Resistance and nothing else.

I agree, X/R=Q Lower Q means more loss.

Proximity effect could cause all of the additional losses.
Or it might just be part of the additional losses.

Why is it that when you get near self resonance of a coil the Q gets lower?
Note; to help clearify my question,

(as you get nearer and nearer resonance the capacitor you are using to tune
the inductor is getting smaller and smaller, and closer to equalling the
self
capacitance of the inductor)

> Remember---Correlation is NOT causality.

If you measure reading skills in an elementary school you will find the
kids with big feet read better.

But then 5th graders usually have bigger feet than kindergarteners.

Thanks for the discussion____

Hi Mike

I am curious about how the comment in your post ---
>It seems I could add capacitors across turns of a coil and increase
> circulating currents that would show as a lower Q. But I haven't
> built a coil to test this.
I would have thought that, when the circulating current increases when a passive devce is introduced, the Q would have Increased.

Jerry

Hi Mike,

This is then a characteristic of the Capacitor called D (dissipation).
Any increase in current tied to loss immediately goes to the bottom
line of resistance - it is a square law relationship, after all.

>>Loss ALWAYS resides in Resistance and nothing else.
>
> I agree, X/R=Q Lower Q means more loss.
>(let's not get into radiation resistance right now)

Why not? Small loops suffer by comparison, and multi-turn loops even
more so.

> Proximity effect could cause all of the additional losses.
>Or it might just be part of the additional losses.

For wire separations beyond 3 or 4 wire diameters, the increase in
skin effect is small. It might be noted that interwinding Capacitance
also falls.

>Why is it that when you get near self resonance of a coil the Q gets lower?
>Note; to help clearify my question,
>(as you get nearer and nearer resonance the capacitor you are using to tune

Again, the answer must reside in Resistance. There are many
characteristics (wavelength, solenoid diameter, length, pitch, wire
gauge, self-capacitance, distributed capacitance, balance,
connections, earth proximity, radiation resistance) being juggled with
small Loop antennas and some (even many) choices that can be made to
resonate the antenna do not lead to an efficient solution.

So your saying yes, the thought experiment would show more loss,
but the loss is in the capacitor. The loss in a capacitor would be
dielectric
and loss in the plates right?

>

I figure it would only confuse the issue.
I was trying to stay away from radiation resistance because my experience of
the effect Bill ask about has been with small aircore inductors. But on
second thought
even those have Rr.

>> Proximity effect could cause all of the additional losses.

Richard, I don't think anyone would disagree that the losses are resistive.
You seem to have answered the question I posted by saying it's increased
resistance.
Yes I agree,
Why does the reistance go up near resonance?

Mike

Hi Mike,

Depending upon construction, most assuredly. However, little loss is found in dielectrics (unless you are using particularly crummy examples). For bad dielectric, you can expects arcs and sparks followed by carbon, and then catastrophic heat accumulation. Most lost is in what is specified in ESR (effective series resistance) which you have already identified as in the plates, but often more in the leads and their connections to the plates. To pack in more capacitance, the trend is for thinner plates for a given package volume. You can guess where the resistance will rise there when the circulating currents are see-sawing in that thin metal.

>>>(let's not get into radiation resistance right now)

> I figure it would only confuse the issue.
>I was trying to stay away from radiation resistance because my experience of
> the effect Bill ask about has been with small aircore inductors. But on
>second thought
>even those have Rr.

The smaller, the worse. It is not so much about the size of Rr, but its relation (ratio) to Ohmic loss. For instance, a 1 meter loop composed of #40 wire is going to be deaf and dumb at 80M, but you might have a chance with 10cM hollow pipe with tight connections. Both exhibit the same Rr, but the wire's Ohmic loss is clearly deadly in comparison to it, than for the pipe's Ohmic loss. Rr in this band, for this size, runs on the order of 0.0075 Ohms.

> Why does the reistance go up near resonance?

I haven't seen that happen. However, for the same resistance, as you approach resonance, the circulating currents climb, and loss is by the square.

Cecil,

So soon we forget. In a standing wave antenna the phase is gone, kaput.
I believe you have even quoted me on occasion when it was convenient for
the purpose you had at the moment.

Since the traveling wave phase exists only in your imagination, just
pick a number that supports whatever you are trying to "prove" now.

5329. Scanned Antennas book by Kraus

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-29 23:01:29 UTC
From: "Dave (from the UK)" <see-my-signature@southminster-branch-line.org.uk>
Message-ID: <463523ca@212.67.96.135>
Source record: 41945

There is a scanned copy of a book you may find interesting:

Antennas, John D. Kraus, Ph.D.., 1950, 553 pages

This book is a college text and engineering reference on antennas. A
pretty thorough theoretical treatment along with practical information
on antenna design.

See

http://www.pmillett.com/Books/Kraus_antennas.pdf (7.9 MB)

More books at

http://www.pmillett.com/technical_books_online.htm

Apparently the copyright has expired on these books, so they are not
pirated. I actually own a copy of the Kraus book, but it is attractive
to have a copy on my laptop.

Very interesting Jim, I hadn't heard that. The rumor that I heard was that his computor was hacked which I thought was strange. None the less I see the law as being unenforceable because copying is difficult to prove and as the music industry has found out the fed courts are not interested in individual prosecutions. Another point that is murky with respect to a copyright is that the complaintant has to illustrate how the offence marred his ability to collect money on his ownership and if there is evidence that financial reward is no longer being pursued the copyright can easily be declared withdrawn. This action can also be taken if a patent is not actively pursued. In both patent and copyright laws the "intent" is to encourage declaration of ones ingenuety for the benefit of all in exchange for the sole right to reap rewards that are being actively sort. During the last decade Congress have acted in the areas of patent law and copyright law which benefitted the former but weakened the latter. Either way the law does provide a method of compensation if the offender has resources, if he hasn't prosecution becomes moot. Morally I see it as wrong to copy what does not belong to you but to enforce moral behavior is a very dicy exercise.

I gave you a little bit of a trick question when I ask,

> The loss in a capacitor would be dielectric and loss in the plates right?

In my inductor the interwinding capacitance is made of a dielectric
(some type of insulation and air) and the plates (made by the wire).
The wire has more current because of that interwinding capacitance,
and as you say "loss is by the square".
Is my argument moving you at all?

Try measureing the Q of an aircore coil close to it's self resonance
(or worse, at self resonance without an additional capacitor)
and then at half that frequency.

>However, for the same resistance, as you
> approach resonance, the circulating currents climb, and loss is by the
> square.
>
I'm defining circulating currents as those that circulate between turns
and don't necessarily go through the capacitor used to resonate the coil.
Does that fit your definition as used in your paragraph above?

Thanks, Mike

And it is again convenient to quote you:

> The only "phase" remaining is the cos (kz) term, which is really
> an amplitude description, not a phase.

You also have said that all the phase information is still there,
that superposition doesn't destroy any information. I believe you.
The standing wave current is a cosine function. The arc-cosine of
the amplitude yields the phase of the component waves.

> Since the traveling wave phase exists only in your imagination, just
> pick a number that supports whatever you are trying to "prove" now.

The point is that this is the very current that Roy used to
"measure" the phase shift through a loading coil. I agree with
you that standing wave current cannot be used to measure the
phase shift through a loading coil. Now if you will tell that
technical fact to Roy, he can withdraw his previous assertions.

It seems that you are contradicting yourself by saying that all
the information in the component waves is still there after
superposition yet you say the phase is gone. Both statements
cannot be true.

This is great, Dave. Everyone who wants to see the standing wave phase shift up and down a 1/2WL antenna can look at page 239. Kraus shows a ~3 degree phase shift all up and down the antenna. EZNEC shows the same thing. Now how did Roy use this current to determine the phase shift through a loading coil if it cannot be used to determine the phase shift through a wire?

5342. Effectiveness of decoupling radials

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-30 03:53:06 UTC
From: Owen Duffy <none@no.where>
Message-ID: <Xns99228D403252Cnonenowhere@61.9.191.5>
Source record: 41958

I have been playing with some NEC-2 models of a multiband vertical with radials.

The vertical is an unloaded vertical of 13m height, and it is mounted on a 6m high grounded metal mast, and an ATU installed at the feedpoint (base of the radiator). I have fitted a pair of opposed nominal quarter wave radials for each of the 80, 40, 30 and 20m bands.

To simulate ground loss, I have modelled a 20 ohm resistance in the bottom of the mast, and used a MININEC ground.

An interesting observation is the sensitivity of this model to length of the radials. Properly adjusted, each pair of opposed radials near eliminate current on the mast (more than 20dB below the current into the radiator). The exception to this is the 30m radials which seem to suffer some interaction with the 80m radials (near third harmonic). Without the appropriate radials, current in the mast to ground is large, and losses can be 10dB or more.

The ideas I take away from the modelling excercise is that:
- inadequate decoupling exacerbates ground loss;
- decoupling is very dependent on the length of the radials;
- one pair of opposed radials is enough for a narrow band;
- the radials for different bands have some interaction; and
- the optimum length may be quite a deal longer than the expected length of legs of a half wave dipole in the same place.

I am grappling with some other way to optimise such a system, other than measuring the mast current (which often isn't easy).

These effects probably also apply to a trapped vertical with similar counterpoise, and the traditional wisdom of tuning either the length of the vertical or radial length to achieve low VSWR is probably less than optimal, there is an optimal length for each of them.

The traditional wisdom that elevated radials are generally significantly lower loss than buried radials probably depends on careful "tuning" or isolation of feed point ground to minimise current flowing to the real ground.

Comments, thoughts?

Owen

The local station here is at 1500 ft + 35ft hi gain vertical at 50W,
with a 2200ft ridge less than 5 miles away... back down to probably
1500 ft until... About 60 miles from here is the tallish 3500ish ft.
mountains and then its down basically to sea level for the remainder.
This does seem to produce a rather sharp angle at the both ends. So
much so that I have trouble hitting the 3500ft repeaters from here
without going up to the big antenna. I do remember hitting some
repeater off to the side of the direct path about 10 years ago with
just a handheld and some gainy portable antenna (don't even remember
which one)... but haven't been able to find it since! Doh!

I'll probably end up just finding some 2m stuff to work. We have a
few linked 440 systems (California) too...

It sounds like I pictured 10 meters as a lot lower that it really is... Sounds like it's really VHF-like during low cycles .. I'll probably go back to 2 or 440 and mess around tho there only a couple repeaters on 2m but a bunch on 440 that are linked.

I am going to try to get at least my dad to upgrade to General tho. I think he'd like to have something long distance while camping, and HF is of course perfect for that :)

Yes, back to experimentation!!

Thanks for all who've responded... Good info!!.

The path I'm lookin for is Oceanside to Redlands, similar to San Diego
to LA, but we have the OC mountains in between... as well as those by
moreno valley...

Time to play with what I have....

"Jimmie D" <GFENDER@carolina.rr.com> wrote:

> A real shame you cant copy and paste text from a pdf file.

I don't know whether you can do this on a Windows computer, but I have been copying text, as well as pictures, from PDF files with my Macs for about as long as there have been PDF files. But to copy text, there has to *BE* text. The Kraus book PDF file, which I have just downloaded, consists of 568 pages of (scanned) pictures.

One can select, as a picture, any portion (or all) of any one page, copy it, and paste it into a document in a graphics program. I just did this with one page of the Kraus "Antennas" book. Such files can be pretty big -- one page produced a 16.2 MB TIFF file which is more than twice as large as the entire PDF file for the Kraus "Antennas" book -- but quite compressible (I compressed that page, losslessly, to 173 kB).

In retirement, for fun and profit, I've been doing pre-publication debugging (for publishers) of math texts written by others. When I receive manuscripts, these are usually sent as PDF files from scans of the actual paper pages produced by the authors. (Paper is used since often scanners, scissors, and Scotch tape are used to produce some of the material in Edition (N + 1) from pages from Edition N.) As such, the files are enormous (thank goodness for a DSL Internet connection) and not searchable -- there's not a single word in such a file, just a succession of pictures, one page at a time. Later in the editing and revision process, I receive PDF files made from TeX files produced by the typesetters which, except for errors needing to be corrected, are ready to print. These files, much smaller than the scanned manuscript files, are searchable, and I can find a word in a few seconds -- much nicer than eyeballing my way through hundreds of sheets of paper, which is the way I did it in the old days ten years ago. At this stage of the game, I can copy and paste text, and I do a lot of that to construct my reports which get sent back to the authors and editors. Needless to say, the reports get sent as PDF files, and the nice thing is that Mac- or UNIX-using authors, Mac users at the typesetting plant, and Windows-using people at the publishing company, can all read my files without any problems.

Hi Owen,

As Reggie would have pointed out at this juncture, tuning of radials in very close proximity to the ground would have been an exercise in futility (that is, expecting a sharp resonance as would be evidenced in elevated radials). As was his wont, his description of radials as lossy transmission lines would have held sway in this analysis.

This, of course, is contingent upon my having understood the implication of the quoted text above relating to tuning radials near the ground (instead of on high).

Source record: 41965

Hi, Everybody,

A short vertical such as for mobile use is capacitive and this Xc is usually tuned out with a shunt coil at the feedpoint. Yet, when I model this with EZNEC I cannot simulate this effect properly. I must be doing something wrong. Does anyone have an EZNEC example showing a shunt matching coil inserted as an EZNEC Load at the feedpoint that they can send me?

Thanks very much.

You have a moving target. Skin effect is shifting as you double/halve
the frequency. What does it mean to compare Q at so disparate
frequencies? Are you exploring an intellectual curiosity or trying to
remedy a defect in application?

>>However, for the same resistance, as you
>> approach resonance, the circulating currents climb, and loss is by the
>> square.
>>
> I'm defining circulating currents as those that circulate between turns
>and don't necessarily go through the capacitor used to resonate the coil.
> Does that fit your definition as used in your paragraph above?

Going between turns can be through a turn-to-turn capacitive coupling,
the magnetic coupling has already been discussed in regard to
increased skin effect due to proximity. Loss still remains the
province of resistance. Your best argument is that Capacitance
exacerbates loss, but it does not cause it.

Richard,

The radials in this case are 4m to 6m above the ground, so should exhibit a fairly clear resonance.

In my experience, the capacitive reactance of a short vertical is usually
"tuned out" with a series inductor (inductance and resistance).

If you do offset all of the reactance, you may have a very low feedpoint
resistance, and that may drive you to consider some form of L match at
the base, the L match formed by a radiator that is not resonated and some
shunt L or C element.

5354. Re: EZNEC Example of Short Vertical w/ Matching Coil

Newsgroup: rec.radio.amateur.antenna
Date: 2007-04-30 09:39:29 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <133beamdgirtpcd@corp.supernews.com>
Source record: 41970

A source and load placed on the same segment are always connected in series. The only ways in EZNEC to simulate a coil in parallel with a source are:

1. Construct a physical model of the coil using wires (if it's an air core coil), and connect it appropriately using wires.

2. Make a small loop of three or four one-segment wires. Put the source in one leg of the loop and a load in another. This is a bit tricky, and doesn't always work -- NEC doesn't like small loops, so there's a minimum practical size. But if the loop is too large, the wires it's made from add reactance and radiate. You might or might not be able to find a size which works. This is one of the very few situations where the double precision calculating engine of EZNEC+ might be an advantage, since it'll tolerate loops which are a bit smaller than the standard engine. You should run an Average Gain test on the antenna to make sure the NEC calculating engine isn't getting unhappy with the small loop.

But as some others have commented, it's much more common to take care of the capacitive reactance of a short whip with a series, rather than shunt, inductor.

I don't know the rules for when copyright expires in different
countries. But I do know that John Kraus died in July 2004. I have the
3rd edition of his "Antennas", it is from 2001. The front matter says
"Copyright 1950, <don't remember>, 2001"

So I am not sure that the 1950 edition is in the public domain.

Kraus was a very interesting character. Invented ham antennas in the
thirties, the helix antenna ca. 1945, central in the development of
radio astronomy, and finally one of the driving forces behind SETI at
home.

Of course, it is much easier to keep up with the times if you shape
them yourself :-)

I agree that skin effect is just one more charactistic that needs to be
added to the mix.

>Are you exploring an intellectual curiosity or trying to
> remedy a defect in application?

No, I just have experienced the effect that Bill ask about and
gave my own pet theory about why it happens.
Now I'm looking for a little confirmation or where I went wrong.

Richard, That's like saying rain has water in it. No matter how many times
you say it,
I'm still going to agree with you.

>Your best argument is that Capacitance exacerbates loss.

I would rephrase that as "interwinding capacitance exacerbates loss".

And with that, you have summed up my argument perfectly.

You have helped reduce my argument to 4 words.

Now, do you agree that interwinding capacitance will reduce Q?
(yes, I know it's the province of resistance)

Thanks, Mike

Owen.

My first thoughts are while such a situation can be modeled, in the
real world I would doubt you can build a system as you describe where
the radials are balance. Just as one can not install a dipole in a
typical back yard (garden) that is truly balanced.

My two cents worth. <G>

You can, but in the case where a book is scanned the pages are handled
as graphics and not text. To do so all pages would have to be
processed using OCR software after scanning which is a major pain and
very time consuming.

Owen, he is probably trying to achieve a feedpoint
impedance of 50 ohms instead of a resonant feedpoint
of 20 ohms. If one makes the feedpoint 25-j25, for
instance, and installs a base shunt coil, one can
twist the feedpoint impedance to 50+j0 ohms using
a +j50 ohm shunt coil.

In like manner, a -j50 base shunt capacitor will
twist 25+j25 to 50+j0 ohms.

The ARRL Handbook describes such shunt matching
techniques in the mobile antenna section.

FWIW, I use the information provided by EZNEC as input to the TLW
program (ARRL Antenna Book) for this set of conditions.

Note that radiation from the matching device is ignored under this
circumstance.

Quoting the ARRL Antenna Book: "The input impedance of
short, high-Q coil-loaded antennas is quite low. For
example, an 8-foot antenna optimized for 3.9 MHz with
a coil Q of 300 and a ground loss resistance of two
ohms has a base input impedance of about 13 ohms."

It is common practice to adjust the feedpoint impedance
to about 13-j22 and install a base shunt inductive
reactance of ~+j30 to twist the feedpoint impedance
to a near perfect 50+j0 ohms.

Just as an aside, Owen, have you considered just a single pair of non-resonant, opposed radials for all bands? The ATU can just as easily "tune" a single radial pair + vertical element as it can the vertical element alone.

Any additional benefit of separate radial pairs for different bands may be slight.

Chuck

Cecil,

Both statements are true. Superposition does not favor one description over the other. If there is no phase information remaining in the superposed result (the standing wave) then there is no phase information remaining at all, regardless of your mathematical manipulations. There are no hidden variables.

Someone else recently pointed out that Mother Nature does not care what models we use; the underlying physical reality will be the same. You continue to try to get around that fundamental principle, but it won't work.

I have such an antenna and am very satisfied with it.
It is a 22 foot vertical with the feedpoint at 22 feet.
Four 22 foot radials slant down at a 45 degree angle
and double as guy wires. An SG-230 is installed at the
feedpoint.

EZNEC says it has a radiation pattern ranging from
0.5 dBi at 22 deg TOA on 40m to 4.2 dBi at 11 deg
TOA on 10m. Come on sunspots!

But you said (and for some unknown reason trimmed):

> The only "phase" remaining is the cos (kz) term, which is really
> an amplitude description, not a phase.

I agree with you. The phase of the underlying forward and
reflected traveling waves can be deduced from the *amplitude*
of the standing wave. Here is a graphic excerpted from the
recently available PDF 1st edition of "Antennas" by Kraus.
EZNEC can also be used with the same results.

http://www.w5dxp.com/krausdip.jpg

As you can see, the current amplitude is a ~cosine function.
The phase of the forward traveling wave relative to a source
wave of 1.0 amp at 0 degrees (EZNEC standard) is an ARC-COSINE
function of the current amplitude. For instance, at 45 degrees
away from the feedpoint, the current is ~0.707 amps. ARC-COSINE
of 0.707 is 45 degrees. You were correct when you said that
the information in the forward and reflected waves is preserved
in the standing waves. Kraus' graphic proves it.

But it has yet to be explained how Roy (and Tom R.) could
use the essentially unchanging *phase* of the standing wave
current to "measure" the phase shift through a loading coil
- since the phase of the standing wave current cannot even
be used to determine the phase shift through a wire. This
question has been asked many times. The absence of an answer
stands out like a sore thumb.

> Roy said:
>> What I measured was a 3.1% reduction in magnitude from input to output,
>> with no discernible phase shift.

Of course there was no discernible phase shift as can be seen from
Kraus' graphic above. But Kraus' graph gives us a way to deduce
the phase shift from the amplitudes. Assuming a reference amplitude
of 1.0 amp at the bottom of the coil, a 3.1% reduction would give
us 0.969 amps at the top of the coil. ARC-COSINE(0.969) = 14.3 deg.
That's a close approximation of the phase shift through the coil
being undergone by the forward current and reflected current.

If the forward current at the bottom of the coil is 0.55A @ 0 deg,
and the reflected current at the bottom of the coil is
0.45A @ 0 deg, the total current at the bottom of the coil
is 1.0A @ 0 deg. With a 14.3 degree phase shift through the
coil, the forward current at the top of the coil would be
0.55A @ -14.3 deg and the reflected current would be
0.45A @ +14.3 deg. Adding those two phasors together yields

0.55A*cos(-14.3) + 0.45A*cos(+ 14.3) = 0.533A + 0.436A = 0.969A
at the top of the coil. 0.969A is 3.1% lower than the 1.0 amp
at the bottom of the coil. Everything is perfectly consistent
with a 14.3 degree phase shift through the coil for the two
traveling waves.

You can copy and paste TEXT from the pdf file. As mentioned the Kraus book
is scanned in the gif fromat and the text you are seeing is actual an image.
To get part of the text out of the gif that is in the pdf file , you have to
treat it as a picture and use the snapshot tool and cut out what you want to
paste into another documment.
What you have done is move part of an image file and not part of a text
file.

Atleast that is how it works with the Adobe Reader 7 and MS word.

Hi Mike,

Well, that is fine and good, but neither of you have given us any real data, and certainly no Q values to judge if what you both experienced was within the range of "normal" or out in left field. RF measurements are difficult to do to any particularly fine accuracy, and what was observed may have been simple variation due to the measurer's proximity (offering just one of many things that can go wrong).

>>Loss still remains the province of resistance.
>
>Richard, That's like saying rain has water in it. No matter how many times

>
>You have helped reduce my argument to 4 words.
>
> Now, do you agree that interwinding capacitance will reduce Q?
>(yes, I know it's the province of resistance)

Give me some metrics to show it is not skin effect.

The issue at hand is your (both you and Bill, or either of you separately) loops keep changing to fit to the loss rather than to the application. It makes for a rather strained progression of design as loops are added, proximity becomes a greater issue, as coil length collapses, insulation is added, and as frequency shifts to follow

these changes. It is as though a good 10M loop is evolving to operate poorly there or, worse, in the 160M band where its resonance has finally come to rest through optimizing for loss.

I can imagine there being enough turn-to-turn capacitance to induce large currents, but so many correlating factors would have to ride along with this that they could easily eclipse that contribution of loss. In other words, it seems the goal of your argument is to raise that capacitance, which by ordinary means has you drawing the loops together (insulated or not). This compounds the skin effect and for a constant frequency demands a lower inductance. The lower inductance, in turn, then demands a smaller coil which forces a lower Radiation resistance. A smaller coil (to again follow the demand for more Capacitance) drives closer loops.

It seems like this is in an infinite regress.

More from my research (which is probably at an end at this point):

Bell, "Fundamentals of Electric Circuits," calls a phasor a rotating
vector, period.

IEEE Standard Dictionary of Electrical and Electronic Terms has
entries for both non-rotating and rotating definintions.

Christiansen, "Electronic Engineers' Handbook," defines a phasor
clearly as a non-rotating quantity.

This has been educational. Clearly there are people in both camps.
I'm obviously in the non-rotating camp, and it seems to be one with a
high population. I'll be careful to ask when someone writes of
phasors and their definition is not clear from the context, at least
if the distinction between the two definitions matters in that case.

Cheers,
Tom

I thought the non-rotating camp was the only one. Because
of that, I need to apologize to Roy, W7EL, who is apparently
in the rotating camp when he said that standing-wave phasors
have a rotational speed the same as the traveling wave. Since
he doesn't read my postings, would you please reply to this
one so he will see it? TNX

In any case, whatever you do, it is unlikely that a single element will
achieve
a match. Unless you are very lucky you will need a two element network.
For example a shunt L, series C, or Series L, shunt L, or series L, shunt
C will achieve a match for virtually any capacitive load. A Smith Chart
is ideal for such analysis.

I don't understand why you think we want more interwinding capacitance,
We want less.
I will agree that the mechanics involved in trying to reduce interwinding
capacitance
will probably reduce proximity effects and so to seperate out any affect
from the
reduces interwinding capacitance would be difficult.
I need to go,
Later, thanks Richard

If the radials are horizontal, the field of the radials cancels out. If the radials are drooping, the radials radiate considerably. Is there any advantage in either configuration? Perhaps for feedline decoupling?

The field pattern will be different between transmit and receive, because in receive mode the radio wave can be coming from the source in any direction. Does antenna reciprocity theorem cover this, as usually people state that the field pattern is the same for transmit and receive?

Hi Frank

My understanding was that the MININEC ground model was the better to use if the model caused current to flow into ground (as mine does).

The draft model is at http://www.vk1od.net/multibandunloadedvertical/13MVERT01.nec if you want to play with it.

That would seem the case if you just regard the radials as providing a counterpoise, the "other" connection that provides a return path for current to the source. I have modelled this scenario where the source is at the feedpoint (ie no transmission line) and the radials and radiator are suspended above ground by a non-conducting structure, and you are right that the radials need not be resonant, residual reactance being dealt with by the auto-tuner at the feed point.

However, if you connect the radials to ground by some conductor (eg feed line and / mast) that conductor is not part of the picture, and as I modelled a conducting mast with a lossy ground connection, the big picture is very different.

Here is a plot of modelled system losses with the configuration that I described: http://www.vk1od.net/multibandunloadedvertical/13mEV03.gif . Not the large losses at 5MHz, this loss is mostly in the 20 ohms equivalent earth resistance. The high ant+gnd loss at 1.8MHz can be reduced to less than a dB with a pair of ~40m long radials (but tuner losses increase to 3+dB).

So it seems that one could do as you suggest and effectively isolate the radiator and radials from ground, or the radials need to be carefully adjusted to minimise the mast / feedline current to ground, especially where the feedpoint resistance is small wrt the equivalent mast to eart resistance.

I agree that practical antennas on suburban blocks are a challenge. But that doesn't eliminate the effects, and I think the key issue that the models raise is the value in effectively decoupling the mast / feed line. Tuned radials are not the only method, and as I suggested in my post, short of measuring the mast current, I cannot see any other obvious method of "tuning" the radials for maximum decoupling.

I find that there are many anomalies in RF theory. For example, Maxwells Equations show reflection at a boundary where current flows in the metal surface down to the skin depth. Books then state that this boundary condition applies to waves guided by two wires. The wires therefore sort of reflect the wave and guide it. Power flows as the Poynting vector.

Current can be a flow of electrons or holes. If the current in a P type semiconductor is holes, it is a flow of emptiness or nothing.

Current is normally said to be the flow of electrons. The electrons actually move very slowly with a drift velocity of a few mm per second. The signal part of the current that flows near speed of light is the electromagnetic wave that flows in the area outside the conductor.

There seem to be a number of disputes in RF e.g. about the effectiveness of conjugate matching with Walter Maxwell refuting articles in his book "Reflections".

RF seems to be a black art e.g. when it comes to S parameters, network analysers, phase matching and batch matching of cables. Little seems to be written down.

But one of those reactances can be supplied by detuning the loaded antenna,
the second typically by a shunt coil.

For example, if the R component at the base at resonance is say 20 ohms
(radiation resistance, equivalent coil resistance and equivalent ground
resistance), detuning the radiator + loading for about 25 ohms of capacitive
reactance will allow a shunt coil of about 2uH to form an L match at 3.6MHz.

The problems you're encountering are the result of trying to oversimplify electromagnetic theory by reducing it to conceptual models which are far from adequate. Your basic conceptual models are faulty, so any conclusions you draw from using these models will eventually lead to contradictions. That same problem has, in fact, been the cause of a huge number of argumentative postings on this newsgroup.

You have a great deal of curiosity about electromagnetic phenomena, so you'd benefit a great deal from a bit of education. To fully understand electromagnetics, you need a solid background in mathematics. Without the solid background of math and electromagnetic theory, you'll always find it necessary to use oversimplified models, and those will always lead to contradictions. It takes considerable time and effort to gain the necessary background, but if you truly want the answers to your questions, it's the only way.

Ok, I'm back.
Richard, I was starting to lean towards proximity effect possibly causing
all of the affect we have been discussing, so I did some Googling. I kept
find the

same line " increased capacitance lowers Q" But, I think you agree that as I said
above most efforts to reduce capacitance will also reduce proximity effect.
I ran across W8JI's page, he's usually pretty exacting in his wording, and he says,

"Capacitance across any inductor carrying time-varying current increases circulating
currents in the inductor, increasing loss while simultaneously reducing system bandwidth."

snip "Anything that increases capacitance will reduce component Q"

He never mentions the correlation between interwinding capacitance and proximity effect

These line were taken from;
http://www.w8ji.com/loading_inductors.htm

What do you think?
Mike

Any elevated radials need to be resonant, and show a low Z at
the freq being used. If they show a high Z, they are basically
useless. You have to think of them more as the lower half
of the antenna, rather than ground radials. I read a post of
Roy's the other day that kind of touched on this. There really
is no "RF ground" when elevated, according to him, and I agree.
It's all one total antenna same as any other.
Of course, the number of radials used for the lower half of the
low GP antenna will greatly effect the ground loss, and to some
extent the decoupling of the feedline.
I've noticed that adding more than four radials to a 1/4 wave GP
on 2m did improve decoupling.
So even if ground losses are not an issue, IE: the 2m example,
the performance can still be improved by improving the decoupling
of the line. And it's noticable too.
But with your low band, low height antenna, ground losses are
a larger issue than decoupling. 2 radials are going to be lukewarm
at best, even elevated at your low height in wavelength.
Your ground losses are going to be pretty high.
MK
